Determinismul genetic al hiperinsulinemiei şi hiperandrogenismul este rar (33). Sunt descrise trei cauze principale ale rezistenţei periferice la insulină. Asocierea rezistenţă periferică la insulină hiperandrogenism şi achantozis nigricans, cunoscută sub numele de "sindrom tip A", poate fi datorată unei mutaţii a genei receptorului pentru insulină, care antrenează scăderea numărului receptorilor în organele ţintă. Leproşonismul (S Donohue) este un sindrom foarte rar ce debutează intrauterin sau imediat postpartum, manifestat prin talie scăzută (defect al receptorilor de creştere), rezistenţa la insulină (mutaţia genei receptorilor insulinici), ovare polichistice, hiperandrogenism, achantozis nigricans şi dismorfisme faciale (lepreschaun=cuvânt din irlandeza veche care semnifică o zână miraculoasă care este întruchiparea unui om bătrân) (34). Sindromul "tip B" constă în prezenţa autoanticorpilor receptorilor pentru insulină. Un alt grup, cel mai larg îl constituie pacientele la care nu se constată, nici anomalii ale receptorilor pentru insulină, nici autoanticorpi antireceptori, dar care prezintă hiperandrogenism şi hiperinsulinemie. Mecanismul posibil constă într-o afectare funcţională a acţiunii receptorului după cuplarea cu insulina.

CONCLUZII

Genele care reglează apoptoza în celulele granuloase sunt activate de factorii externi sau pot fi independente de factorii de mediu, factorii apoptotici şi cei de supravieţuire aflându-se în echilibru instabil. Controlul acestora de către diverse gene (Bcl2 antiapoptotică, gena codantă a ciclinei D2, a enzimelor steroidogenetice, a fosforilării serinei lanţului beta a insulinei, a enzimei Calpain 10, a factorilor de creştere intraovarieni) este încă neelucidat. Cert este că mediul intracelular determină responsivitatea celulelor granuloase la FSH, influenţând apoptoza acestora.

Etiopatogenia sindromului ovarului polichistic este complexă şi obscură, deoarece sindromul nu reprezintă o singură boală. Se admite că anomaliile genetice sau de reglare a unor factori de creştere intraovarieni, pot interveni în producerea sindromului determinând un exces de androgeni produs de suprarenală sau ovar, o secreţie anormală de LH, anomalii enzimatice sau intraovariene în sinteza steroizilor ovarieni şi hiperinsulinism.

NOUTĂŢI

Escherichia coli O157 : H7 un pericol pentru cord şi rinichi

În primăvara anului 2000 reţeaua de alimentare cu apă din Walkerton, Ontario (Canada) a fost contaminată cu *E. coli* O157 : H7 şi *Campylobacter spp.*, rezultând 2300 de gastro-enterite, peste 750 de consultaţii în urgenţă, 65 de spitalizări, 27 de sindroame hemolitice şi uremice şi 7 decese. În 2002 a fost iniţiat un studiu de cohortă prospectiv (Walkerton Health Study), pentru a determina efectele pe termen lung ale acestei contaminări. Din cei 2000 de subiecţi recrutaţi pentru studiu, 1067 (54%) au fost infectaţi cu *E. coli O*157 : H7 şi *Campylobacter spp.*, 403 subiecţi (38%) prezentând o HTA pe parcursul supravegherii, faţă de 294 subiecţi (32%) necontaminaţi (Hazard Ratio HR = 1,33, interval de încredere 95% II 95% : 1,14-1,54). Riscul de patologie cardiovasculară (infarct, AVC sau insuficienţă cardiacă congestivă) a fost şi el crescut pentru subiecţii contaminaţi (HR = 2,13, II 95% : 1,03-4,43). Afectarea renală a fost confirmată prin dozarea microalbuminemiei (albumină /creatină > 2,0 mg/mmol pentru bărbaţi şi > 2,8 mg/mmol la femei) şi evaluarea filtrării glomerulare (> 60 ml/mim/1,73 m^2). Deşi doar 30 de subiecţi au prezentat modificarea simultană a ambilor parametri, aceştia au provenit în majoritate (22/8) din grupul subiecţilor infectaţi (HR3,41, II 95% : 1,51-7,71). Datele prezentului studiu impun o supraveghere atentă a pacienţilor care au prezentat în antecedente o gastroenterită acută simptomatică cu *E. coli O*157 : H7, recomandându-se controlul anual al tensiunii arteriale şi o supraveghere atentă a funcţiei lor renale. Epidemiile cu *E. coli O*157 : H7 sunt semnalate din ce în ce mai des în toată lumea : în SUA sunt semnalate anual 50000-120000 de gastroenterite acute şi 60 de decese. (Clark F et al. Long term risk for hypertension, renal impairement, and cardiovascular disease after gastroenteritis from drinking water contaminated with *E. coli O*157 : H7 : a prospective cohort study. *BMJ* 2010, 341 : c6020).

INTRAPANCREATIC ACCESSORY SPLEEN: DIAGNOSTIC CHALLENGE AND REVIEW OF DATA FROM THE SPECIALTY LITERATURE (Abstract): Intrapancreatic accessory spleen is a diagnostic challenge requiring a differential diagnosis with retroperitoneal tumor, neuroendocrine pancreatic tumor, pancreas adenocarcinoma. We present a rare case of intrapancreatic accessory spleen, which was radiologically diagnosed as a pancreatic tumor. This is a 37-year-old female patient who showed fluctuating values of CA19-9 tumor marker. Initially, the endoscopic examination of the digestive tract (upper digestive endoscopy, colonoscopy) was performed, excluding the presence of a proliferative process at this level. In order to investigate the small intestine and other abdominal-pelvic organs we performed the abdomen-pelvic CT examination and the MRI examination. Hepatosplenic scintigram was performed to complete the investigations. The intrapancreatic accessory spleen should be considered as a differential diagnosis for pancreatic tumors. Complex paraclinical investigations (EDS, Colonoscopy, CT, MRI, Scintigraphy) can help diagnose and prevent surgical procedures that are not absolutely necessary. **Keywords**: INTRAPANCREATIC ACCESSORY SPLEEN, PANCREATIC TUMOURS.

The pancreas comprises a head, neck, body and tail. It lies retroperitoneally, separated from the stomach in front by the lesser sac. The spleen is the largest organ of the lymphatic system positioned between the fundus of the stomach and the diaphragm in the left hypochondriac region of the abdominal cavity, relatively below the left costal margin between the ninth and 11th ribs (1). Mesenchymal cells are the source from which the spleen is derived from, which are located between the tiers of the dorsal mesogastrium as early as the fifth and sixth weeks of fetal development (1). The rotation of the stomach during embryonic development causes the left mesogastrium surface fusion with the peritoneum above the left kidney and the resultant dorsal attachment of the lienorenal ligament. The yolk sac wall and near dorsal aorta are the sources of the cells needed for the hemopoietic function of the spleen. By

the second trimester, the spleen is capable of both RBC and WBC generation (1).

CASE PRESENTION

We present a rare case of intrapancreatic accessory spleen, which was radiologically diagnosed as a pancreatic tumor. This is a 37-year-old female patient who showed fluctuating values of CA19-9 tumor marker. Initially, the endoscopic examination of the digestive tract (upper digestive endoscopy, colonoscopy) was performed, excluding the presence of a proliferative process at this level. In order to investigate the small intestine and other abdominal-pelvic organs we performed the abdomen-pelvic CT examination and the MRI examination. Hepatosplenic scintigram was performed to complete the investigations.

The abdomen-pelvic CT examination

The abdomen-pelvic CT examination reveals a normal pancreas that contains two well-defined nodular formations located in the caudal pancreas: a distal one in contact with a descending colon loop situated postero-inferior to the splenic hilum, and dimensions of 26/21.5/11.5 mm (AP/T/CC), one located anterior, in the vicinity of the splenic hilum and having dimensions of 13/9.2/10 mm (AP/T/CC) (Fig.1,2). The aspect of the lesions of the caudal pancreas may be suggestive of pancreatic ectopic tissue / neuroendocrine tumor.

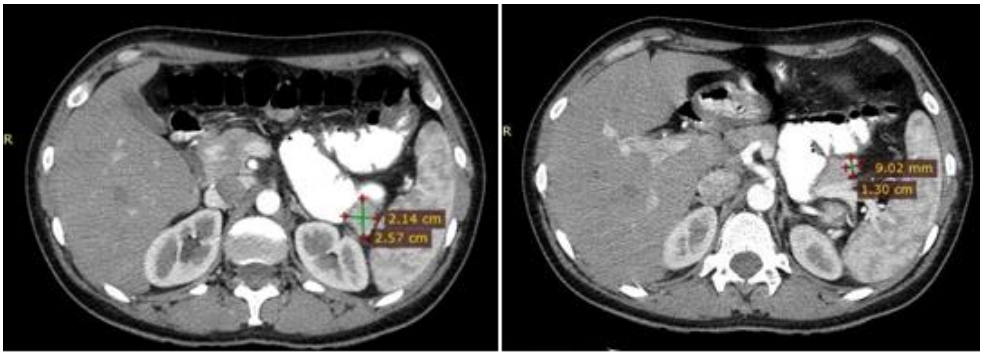

Fig. 1. The abdomen-pelvic CT examination-transverse section reveals a normal pancreas that contains two well-defined nodular formations located in the caudal pancreas

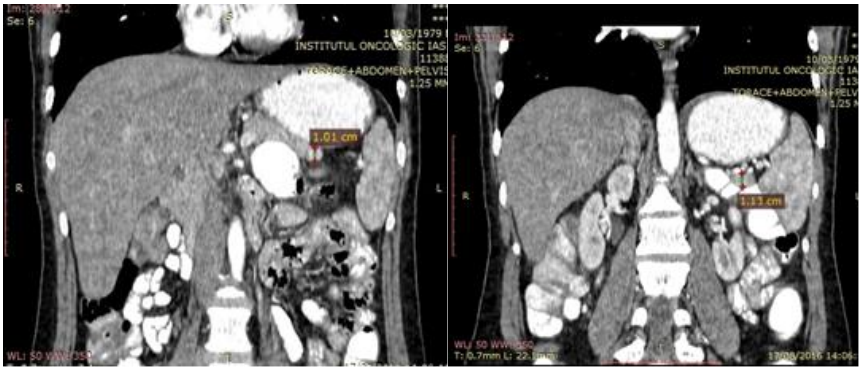

Fig. 2. The abdomen-pelvic CT examination-longitudinal section reveals a normal pancreas that contains two well-defined nodular formations located in the caudal pancreas

The MRI examination

Native MRI examination and MRI examination with contrast substance: pancreas with normal size, lesion in T1, intermediate T2 signal located on the topography of the pancreatic tail with diameter of 12 mm (fig. 3).

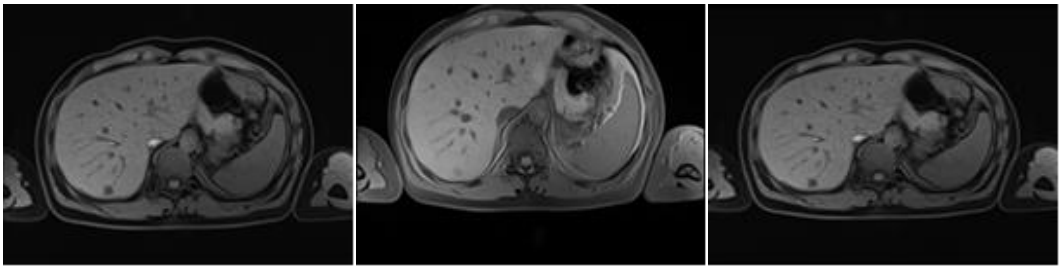

Fig. 3. MRI examination: solid lesion, net contoured, probably benign, caudal pancreas.

Hepato-splenic scintigraphy with 99mtc + NANOCOLL

Scintigraphy performed with 99mTc-NANOCOLL, 5 mCi, administration intravenous. The acquired images were: entire body; images in the abdomen, acquisition in dynamics in the first 5 minutes, SPECT and static (before and after the SPECT acquisition). The images showed the following (fig. 4, 5, 6):

- the heterogeneous hepatic fixation of the radiopharmaceutical (which may be related to the images suggestive of hepatic hemangiomas described in CT);
- fixation in the projection area of the spleen, which is homogeneous;
- on the anterior images and SPECT, medial of the splenic image, in an area that projects in the pancreatic caudal region, one can see a discreet fixation of the radiopharmaceutical, which is individualized and has a rounded contour and whose fixation decreases discreetly over time.

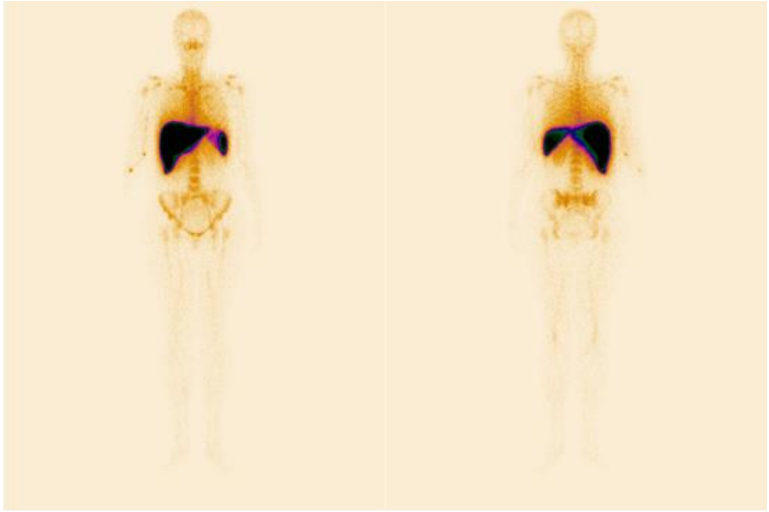

Fig. 4. Scintigraphy performed with 99mTc-NANOCOLL – whole body

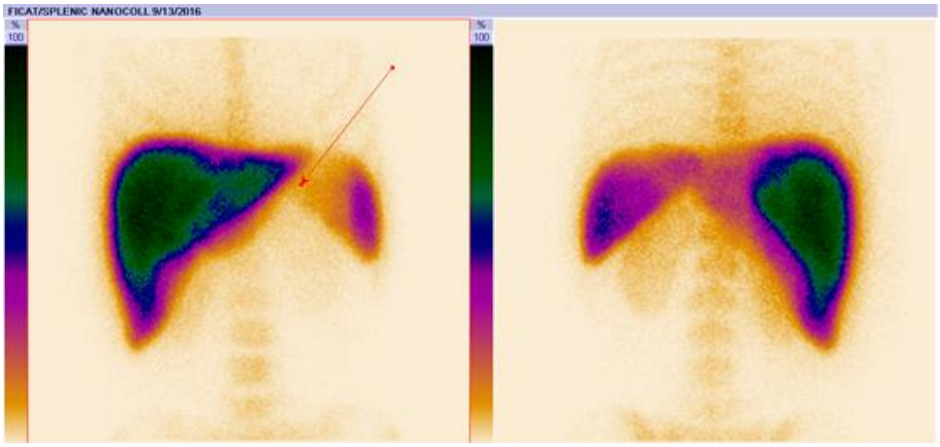

Fig. 5. Scintigraphy performed with 99mTc-NANOCOLL

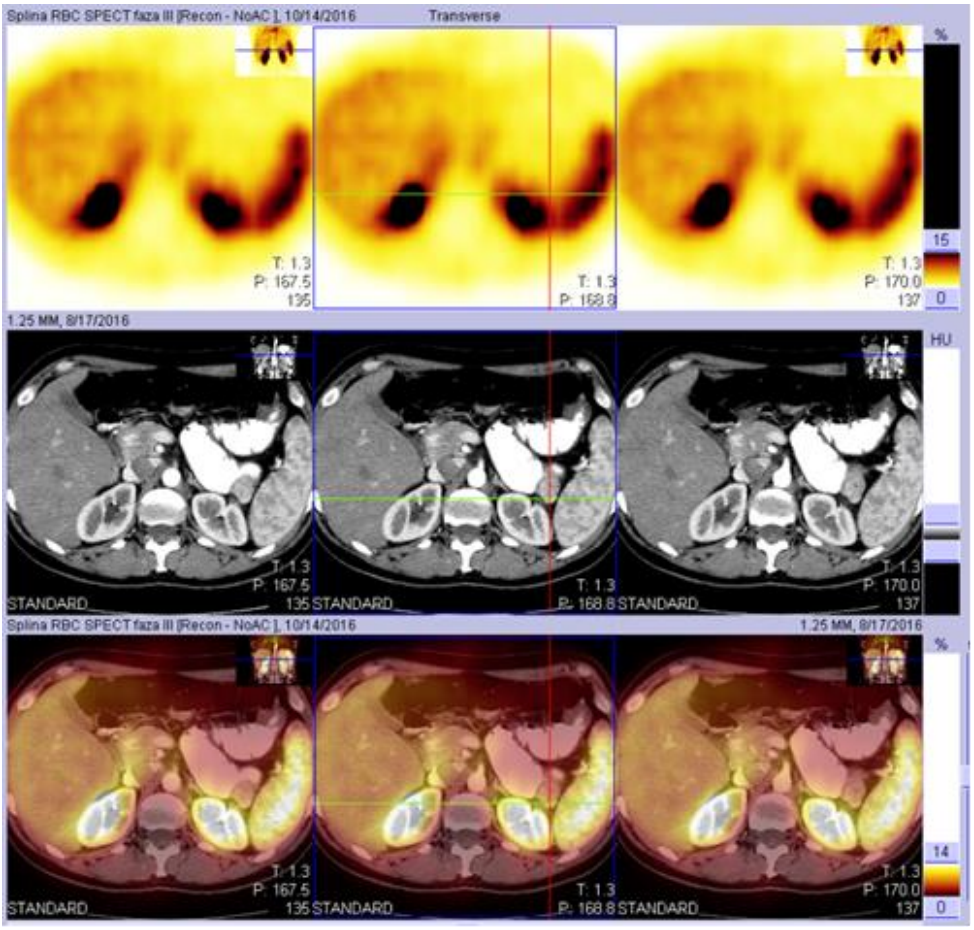

Fig. 6. Scintigraphy performed with 99mTc-NANOCOLL and CT images – Overlay

Conclusions of the hepato-splenic scintigraphy examination with 99mTc + NANOCOLL:

- Given the localization mechanism of the radiopharmaceutical, this image may be suggestive of an accessory spleen, as it would correspond to the formation identified on the CT images.
- We recommend confronting the images with splenic scintigraphic images with marked red blood cells (99mTc – PYP) and possibly with PET-CT images, to exclude with certainty a tumor of pancreatic nature.

Red blood cells scintigraphy marked with 99M TC-PYP

Hepato-splenic scintigraphy with red blood cells marked with 99mTc PYP (in vivo method), static and late static images, SPECT and the fused images SPECT-CT and SPECT with 99mTc PYP and SPECT with 99mTc Nanocoll, showed: very discrete fixation images of radiopharmaceutical in the projection area of the two formations identified on CT and images with 99mTc NANOCOLL.

Although the fixation is very small corresponding to the fixation in the spleen area, it is larger than the background noise (according to the quantification on the fused image).This low degree of fixation could be explained by the small size of the formations and, therefore, the small amount of tissue that would have to seize the marked red blood cells, in the situation of a spleen accessory tissue (fig. 7, 8)

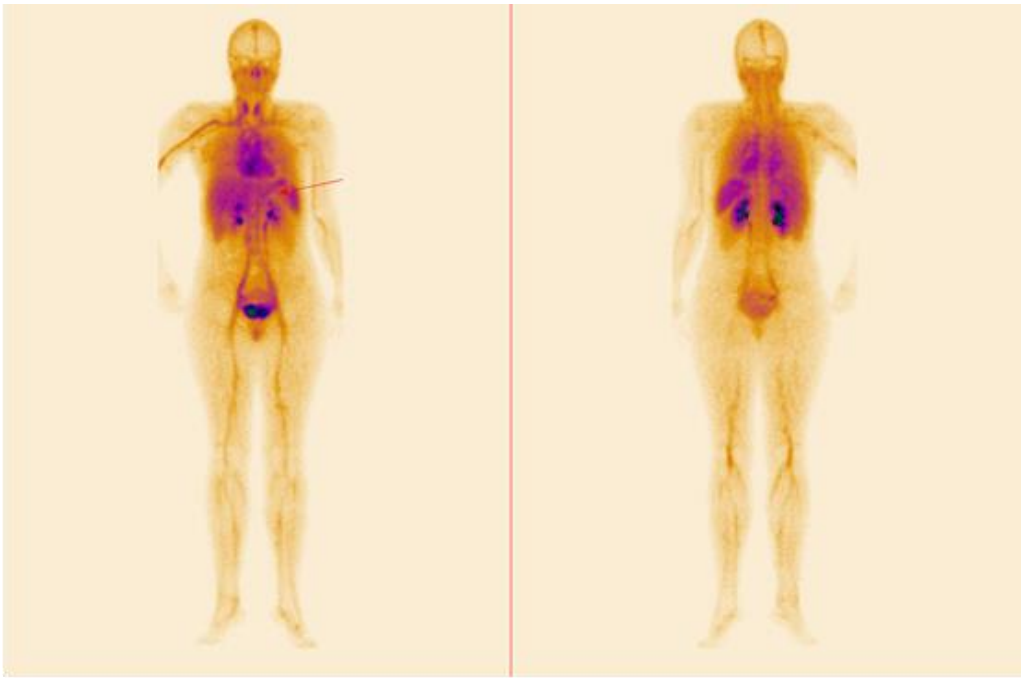

Fig. 7. Hepato-splenic scintigraphy with red blood cells marked with 99mTc PYP-whole body.

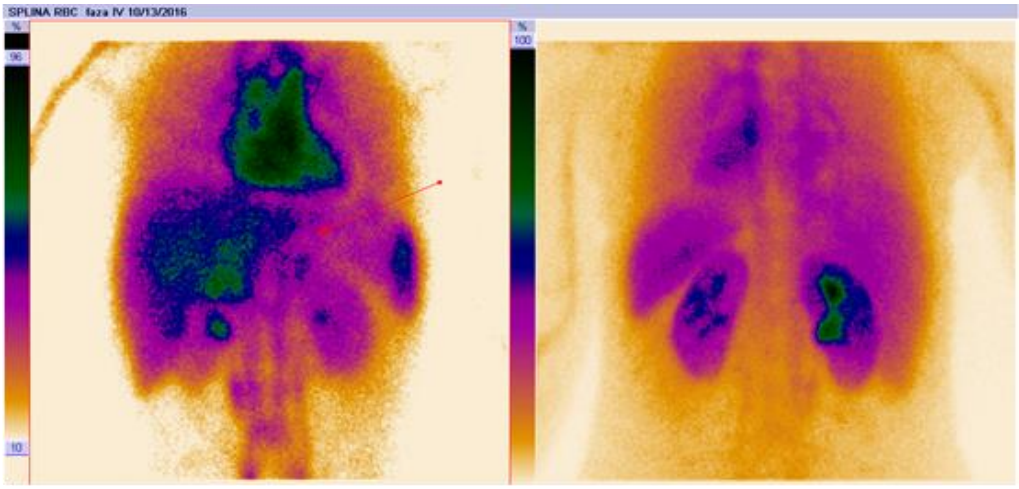

Fig. 8. Hepato-splenic scintigraphy with red blood cells marked with 99mTc PYP

DISCUSSION

The accessory spleen can be found relatively frequently in the general population - 10-15% according to the necroptotic results and according to other authors up to 20%. Among these, only 1-2% are located intrapancreatic (pancreatic tail), the majority being located in the splenic hill (2-5)**.** The accessory intrapancreatic spleen is a congenital anomaly in which there is a failure between a portion a splenic tissue and the main body of the spleen during the embryological development. The spleen appears at approximately the sixth week of embryologic life as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end. The proliferating cells invade the underlying angiogenetic mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas, which soon fuse to form a lobulated spleen. In the subsequent periods of embryologic life, the earlier lobulated character of the spleen disappears but is indicated by the presence of notches on its upper border in the adult (6, 7). The accessory spleens ca be named also splenunculus (8).

Intrapancreatic accessory spleen is a diagnostic challenge requiring a differential diagnosis with retroperitoneal tumor, neuroendocrine pancreatic tumor, pancreas adenocarcinoma. The accessory intrapancreatic spleens are commonly presented as a hyper vascular node in the tail of the pancreas on abdominal CT and MRI, mimicking a tumor of the pancreas or pancreatic neuroendocrine tumor (10). An intrapancreatic accessory spleen (IPAS) is usually less than 3 cm in size and is generally an unexpected condition (11).

Although majority of the studies showed no clinical symptoms in patients or no pathological blood tests, in our case we found an elevated level of CA 19-9. This made hard to do differential diagnosis with a pancreatic tumor. Conclusions for red blood cells scintigraphy exam marked with 99mTc-PYP: there is a possibility that the formations described on the CT, and which show discrete fixation of 99mTc NANO-COLL (which would suggest a tissue structure with the retico-endothelial component) and discreet seizures of red blood cells

marked with 99mTc PYP to represent accessory spleen tissue, especially since the data from the literature suggest that histopathological there may be a relative variation in the accessory spleen tissue (for example intralesional cysts-which may even be associated with a growth of the seric CA 19-9 (12). The evolutive follow-up of these lesions by structural imaging methods, in a clinical and paraclinical context is required.

CONCLUSIONS

The intrapancreatic accessory spleen should be considered as a differential diagnosis for pancreatic tumors. Complex paraclinical investigations (CT, MRI, Scintigraphy) can help diagnose and prevent surgical procedures that are not absolutely necessary.

Knowledge of anatomy of spleen is fundamental to the radiologists during diagnostic procedures to prevent interpretation errors in diagnostic imaging.

THE INFLUENCE OF MEDICAL EDUCATION ON MEDICAL STAFF COMPLIANCE WITH HAND HYGIENE GUIDELINES (Abstract): The objective of the study was to estimate the influence that continued medical education has on the correct disinfection of the hands during the work of different categories of medical staff. **Material and method:** The research was based on direct observation of the correctness of the hand disinfection, according to the WHO recommendations and the experimental validation of the hand disinfection rate using the Semmelweis Scanner developed by HandInScan. The study group included 553 physicians, nurses and auxiliary staff, from 6 hospitals located in Brasov. Data processing was carried out with iNZight software, through descriptive and interference statistics, *Chi-square test* and graphical view. The variables taken into consideration were medical education on hand hygiene, occupation, length of service, age and hospital profile. **Results** are in line with previously data published in literature and the *Chi square test* value (6.4756) confirms the hypothesis that the correct practice of hand disinfection depends on occupation. **Conclusions**: Young subjects and staff from surgical units are more compliant to the correct grasp of the 6-step technique in disinfecting the hand, compared to other age categories or other medical specialties. We recommend the development of a daily alert system for the permanent awareness of the medical staff regarding the frequent practice of hand disinfection. **Keywords**: HAND DISINFECTION, HOSPITAL, PHYSICIANS, NURSES, AUXILIARY STAFF, COMPLIANCE.

The share of healthcare-associated infections in developing countries is high compared to developed countries, thus requiring improvement in surveillance and infection control practices (1, 2). Although hand hygiene as a good medical practice in the hospital that prevents nosocomial transmission of germs is recommended by the WHO as a gold standard, compliance is usually modest (3, 4). The results of some research suggest that compliance with the rules of hand disinfection is significantly influenced by the behavior of medical staff and less by hospital amenities, such as the increased number of washbasins in the hospital rooms or the number of dispensers (5). Hand hygiene (HH) rates remain low among healthcare workers, despite the emphasis placed by trainers on the importance of hand hygiene (6, 7). Even when the staff is aware of being watched if they comply with the rules of hand hygiene and the disinfection technique is correct, the studies note that compliance rates do not change, remaining low (8).

Although there are entire chapters in the education curriculum on the importance of disinfecting teguments and performing correct disinfection techniques, reality shows that without control, education does not yield sustainable. At the individual level, it is necessary to augment a positive attitude towards hand hygiene, respecting the 6 mandatory steps in achieving a proper disinfection technique and reinforcing the belief that each individual can influence the professional behavior of the group to which it is contributing by improving compliance (9).

MATERIAL AND METHODS

This study was conducted in 6 hospitals from Brasov, on a group of 553 subjects, medical and auxiliary staff. The hospitals that participated in the study are including 3 emergency hospitals. Regarding the profile, 3 are single specialty hospitals and 3 multidisciplinary hospitals (including medical and surgical activities). Of the 6 hospitals covered by the study, 5 are state hospitals and only one is a private hospital. Of the 5 state hospitals, 4 are clinical hospitals, where educational activities are also under way, like training of future physicians and nurses.

The research was carried out by the method of direct observation of the correctness of hand disinfection without prior training and validation of the successful technique through the Semmelweis Scanner device. This device indicates the correct disinfection technique, when the surface coverage of hands with disinfectant exceeds 95%, which is considered as success rate. All values below 95% were interpreted as failure rate.

The criteria for inclusion in the study were as follows: the person has to be employed in the hospital, occupation (medical or auxiliary staff) and their participation agreement.

Two hypotheses were issued:

- Hypothesis 1: To what extent successful hand disinfection is influenced by occupation, age, seniority at work, medical or surgical profile of the activities.
- Hypothesis 2: Medical education continues to be valuable in time and significantly influences the hand disinfection technique.

The database was created in CSV format and the processing was done with iNZight software, developed by Professor Christopher J. Wild from the Department of Statistics at the University of Auckland, New Zealand.

RESULTS

Physicians participating in the study, working in medical or surgical specialties, are generally aged between 20 and 30 years and between 60 and 70 years respectively. The nurses working in the medical field department belong to the age group of 31-40 years, 61-70 years, compared to the ones working in the surgical specialties sector, who belong to the age group of 31-40 years. Auxiliary personnel in surgical or medical sections belong to the 51-60 age group. The lot is balanced on the two specialties, surgical and medical.

To all three professional studied categories were analyzed the following variables: hand hygiene course, correct and incorrect disinfection technique. It has been noticed that the highest rate of success in hand disinfection is done by nurses with a hand hygiene course. For auxiliary staff, the rate of failure in performing the disinfection technique is higher regardless whether they have taken a hand hygiene course or not. In the case of physicians, the success rate is higher regardless of whether or not the hand hygiene course is completed.

The distribution of medical staff by age groups, occupation and attendance to course of Hand Hygiene (HH) is presented in first figure.

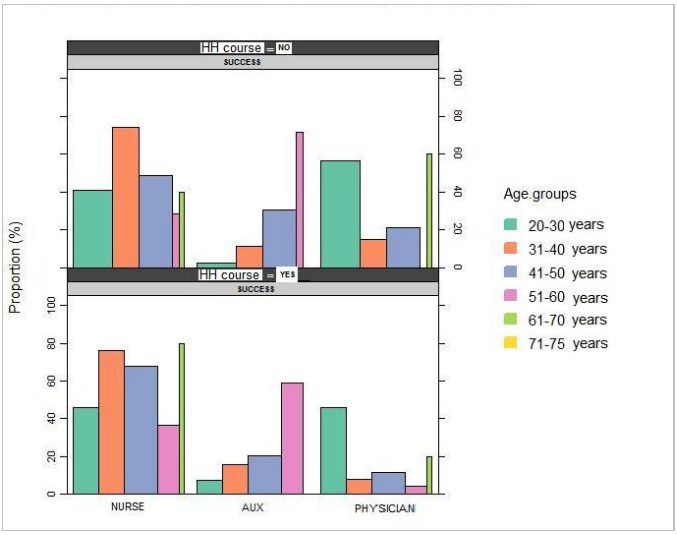

Fig. 1. Distribution of medical staff by age groups, occupation and attendance to Hand Hygiene course

Figure 2 shows the distribution of the comparative lot and the success rate. In 223 study participants, the hand disinfection cover area exceeded 95%, noted as the success rate, and in 330 subjects hand disinfection was incorrectly recorded as a failure rate. 112 people had performed the hand hygiene course and had successful disinfection rate of the hand. 111 people did not take the hand hygiene course but had a successful hand disinfection rate. 213 had not performed the hand hygiene course and had failed to disinfect hands. The highest rate of success is at nurses who attended the hand hygiene course.

The *Chi square test* (value 6.4756) confirms the hypothesis that the correct practice of hand disinfection depends on occupation. The p value was less than 0.05. In the same time, the *Chi square test* value demonstrates that the hand hygiene course influences differently the categories of people studied regarding the success or failure of the hand disinfection technique.

Chi-square test for equal distributions.

- Interference of the distribution by occupation (physician, nurse, auxiliary staff) (columns), by HH course (rows), for experiment success or unsuccess.
- Null Hypothesis: distribution of occupation (physician, nurse, auxiliary staff) does not depend on HH course.
- Alternative Hypothesis: distribution by occupation (physician, nurse, auxiliary staff) changes with HH course X^2=6.4756, df=2, p-value=0.039249.

The analyzed variables were seniority in work and correct hand disinfection technique. It has been noticed that the success rate is influenced by the seniority in work, namely all professional categories with a less seniority in work have a higher success rate. Low compliance has been registered with nurses with the highest seniority in work. In the case

of physicians, the rate of success has been among the young persons, with a lower seniority in work. Analyzing the successful hand disinfection rate, depending on the surgical or medical profile, there was an increase in the success rate for surgical specialties as opposed to medical ones.

Figure 3 summarizes the distribution of the study group with a success or failure rate by age groups and seniority in work. The highest compliance is highlighted in the group of 20-30 years. It is reconfirmed that professional categories with less seniority in work have a higher success rate.

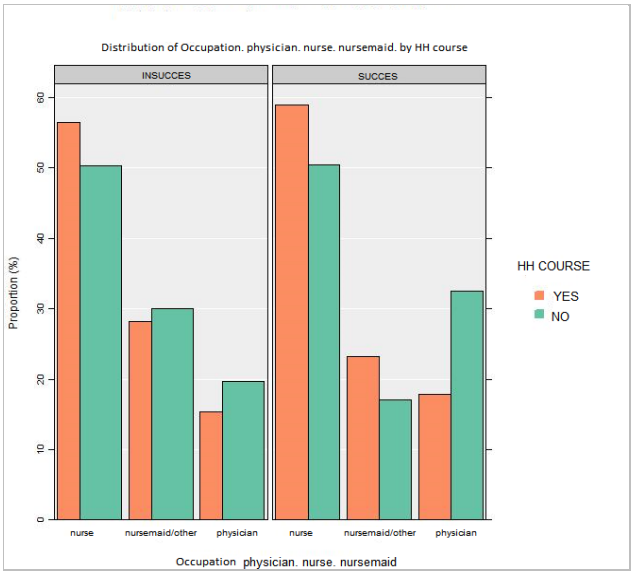

Fig. 2. Distribution of the study group by the rate of success or failure occupation and attendance HH course

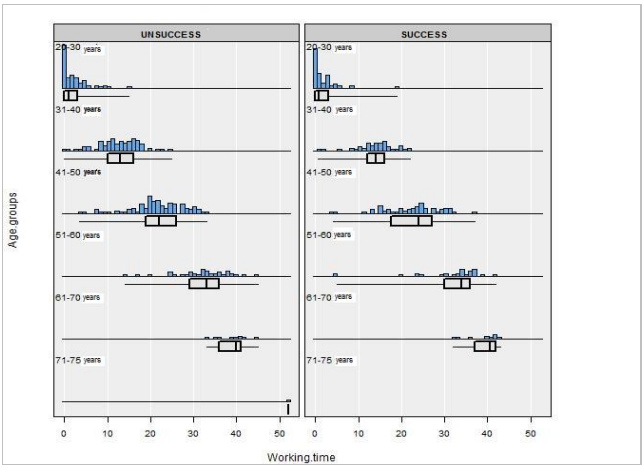

Fig. 3. Distribution of the study group with a success or failure rate by age groups and seniority in work

DISCUSSION

The effectiveness of medical education courses on hand hygiene is different for the subjects included in the study. Thus, in the case of physicians, the success rate is higher regardless whether or not hand hygiene course was completed, as explained by the knowledge gained during university studies. For nurses, the highest rate of success in disinfection is the one with the completed hand hygiene course, to which it is added the right technique that has been learned and practiced repeatedly during the schooling. The highest failure rate in hand disinfection is recorded by the auxiliary staff, whether they have a course or not, which raises the questions whether the hand hygiene course is adequately taught, and it is easy to understand for this professional category. The success rate in getting the right techniques for hand disinfection is higher for respondents with less seniority in work, for 10 years regardless of the profession exercised. This is supported by the willingness to have a higher compliance the more you are new in the profession, which is reconfirmed after the analysis of the success rate according to age groups and seniority in medical practice.

In the case of surgical specialties, all staff categories are more compliant with the hand hygiene concept than physicians, nurses and auxiliary staff who practice in medical specialties.

The specificity of their activities grants a greater importance to the following of aseptic and antisepsis techniques, hospital acquired infections being a possible and serious consequence.

CONCLUSIONS

Young subjects are more compliant with the correct grasp of the 6-step technique in disinfecting the hands, compared to the other age categories.

Staff from surgical specialties is more compliant with hand hygiene concept than the staff practicing in medical specialties.

We recommend the development of a daily alert system for the permanent awareness of the medical staff regarding the frequent practice of hand disinfection.

NEWS

THERAPY FOR PULMONARY ARTERIAL HYPERTENSION IN ADULTS. UPDATE OF THE CHEST GUIDELINE AND EXPERT PANEL REPORT

Pulmonary arterial hypertension (PAH) carries a poor prognosis if not promptly diagnosed and appropriately treated. The development and approval of 14 medications over the last several decades have led to a rapidly evolving approach to therapy, and have necessitated periodic updating of evidence-based treatment guidelines. This guideline statement, which now includes a visual algorithm to enhance its clinical utility, represents the fourth iteration of the American College of Chest Physicians Guideline and Expert Panel Report on Pharmacotherapy for PAH. The guideline panel conducted an updated systematic review to identify studies published after those included in the 2014 guideline. A systematic literature search was conducted using MEDLINE via PubMed and the Cochrane Library. The quality of the body of evidence was assessed for each critical or important outcome of interest using the Grading of Recommendations Assessment, Development and Evaluation approach. Graded recommendations and ungraded consensus-based statements were developed and voted on using a modified Delphi technique to achieve consensus. Two new recommendations on combination therapy and two ungraded consensus-based statements on palliative care were developed. An evidence-based and consensus-driven treatment algorithm was created to guide the clinician through an organized approach to management, and to direct readers to the appropriate area of the document for more detailed information. Therapeutic options for the patient with PAH continue to expand through basic discovery, translational science, and clinical trials. Optimal use of new treatment options requires prompt evaluation at an expert center, utilization of current evidence-based guidelines, and collaborative care using sound clinical judgment (James R. Klinger, C. Gregory Elliott, Deborah J. Levine, Eduardo Bossone et al. *CHEST* 2019; 155(3): 565–586).

DEPRESSION, ANXIETY AND STRESS AMONG MEDICAL STUDENTS

DEPRESSION, ANXIETY AND STRESS AMONG MEDICAL STUDENTS (Abstract): **The aim** of the study is to gather some data regarding the levels of depression, anxiety and stress among medical students. **Material and methods**: a number of 190 students provided answers to an online questionnaire. A socio-demographic data sheet and a psychological tool were administrated (Depression, Anxiety and Stress Scale - *DASS 21*). Data were analyzed using *SPSS program, version 21*. **Results**: The mean age for the sample is 21.38 (±2.18), with a majority of female participants (79.5%). *Independent samples t Tests* showed statistically significant differences between male and female students concerning depression ($t(88) = 4.40$, $p < .001$), anxiety ($t(88) = 4.25$, $p < .001$) and stress ($t(88) = 4.70$, $p < .001$). More specifically, women scored higher than men on all subscales of the *DASS-21*: depression (Mwomen = 18.58, Mmen = 10.92), anxiety (Mwomen = 14.95, Mmen = 7.94) and stress (Mwomen = 15.37, Mmen = 7.48. The results showed significant negative correlations between the three scales of the *DASS-21* and the hours students sleep per night: depression ($r = -.253$, $p < .001$), anxiety ($r = -.210$, $p = .004$), and stress ($r = -.249$, $p = .001$). Statistically significant differences in stress according to participants' body mass index were also identified. Students who rate themselves as consuming alcohol and carbonated drinks more frequently also score higher on depression**. Conclusions**: Stress, anxiety and depression are a real problem for medical students during their academic training. **Keywords**: MEDICAL STUDIES, STUDENTS, DEPRESSION, ANXIETY, STRESS, DASS-21, BMI.

Medical students are at risk for stress and burnout as medicine is a never-ending path and a career with high demands (1). It is widely accepted that medical studies entail a great amount of stress due to tremendous workload and great intellectual and emotional demands (2).

There are two categories of factors that can generate different levels of stress (3): endogenous (sex, personality traits, believes) and exogenous. Exogenous factors are divided into three categories: *academic stressors* (difficulties with understanding and learning new syllabus, difficulty with reading textbooks particularly if there is lack of a premedical university preparatory program (UPP), high workload, extensive medical curricula, long teaching hours, lack of leisure or recreation times; the poor quality of the educational process at the college; irregular schedules, frequency of tests, competition with peers and worries related to academic performance or achievement/ fear of failure), *psychosocial*

stressors (the high paternal expectations; home sickness; the new living accommodation; financial strain; fear of future failure in medical career), and *socio-demographic stressors* (gender; smoking; substance abuse, marital status; working during the study; the levels of parents' education; cultural background and the socioeconomic status of the family).

These stressors can trigger various mental health problems (3-6) and students cope by listening to music, talking to relatives or people close to them, resting or engaging in sports (7).

Of great concern is the fact that, of the students who screened positive for depression, only a low percentage sought psychiatric treatment: 15.7%, identified by Rotenstein *et al.* (8) and 12.9% by Puthran *et al.* (9).

Elliot and Tan (10) found that medical practitioners are also hesitant about seeking help when having mental health problems and the authors reported several barriers to help-seeking: concern about letting colleagues down; concern about stigma; concerns about losing medical staff privileges; concerns about losing medical license; negative impact on practice; confidentiality; letting patients down; letting colleagues down; lack of locum cover and career progression.

The rates of depression, anxiety and stress among medical students – results from different countries

GERMANY. Wege *et al.* (2) found, in a sample of German medical students, a 4.7% prevalence rate for major depression and 5.8% for other depressive symptoms. In their study, expected financial difficulties were associated with por mental health (major depression, other depressive symptoms, anxiety, panic disorders and psychosomatic symptoms). Also, in Burger and Scholz's (11) study, female medical students presented higher scores of depressiveness than male students.

EGYPT. Fawzy and Hamed (3) reported high frequencies of depression (65%), anxiety (73%) and stress (59.9%) among 700 Egyptian medical students. This high prevalence was found to be in relation to sex (being a female), living condition (away from families), the year of study (preclinical years) and academic achievement (poor academic achievement degrees).Wahed and Hassan (12) mentioned that 60.8% of the students in their sample had depression and higher depression scores were associated with increasing age, low socioeconomic standard and other governorates.

UNITED STATES OF AMERICA. In a study conducted by Wimsatt *et al.* (13), 14.7% of students reported a previous depression diagnosis. Moreover, most students declared that they would feel embarrassed if they were depressed and their colleagues knew. Moreover, Hardeman *et al.* (14) found that African American students had a 59 % greater risk of being classified as having depressive symptoms than White students and female medical students had a 39% greater risk of being classified as having depressive symptoms than male students.

Mousa *et al.* (15) found that 15.1% and 15.9% of postgraduates as well as 16.4% and 20.3% of medical students screened positive for major depressive disorder and generalized anxiety disorder. Also, both categories believe depression affects their academic performance (33.3% and 32% respectively). Additionally, according to Ludwig *et al.* (16), students in their third year of study are significantly at risk for

depression compared to their first year.

Wolf and Rosenstock (17) reported that 8% of students screened positive for depression at the beginning of the year and 9.3% in the middle of the year, with a positive association between burnout and depression. Also, the authors found positive depression screening, pathological sleepiness, and sleeping less than 7 hours by night to be independent predictors of burnout.

INDIA. Kumar *et al.* (18) reported an overall prevalence of depression of 21.50% in medical dentistry students. In their study, 3rd and 4th year students showed a significantly higher prevalence of depression than other years. The study of Iqbal *et al.* (19) revealed that 17.5% of medical undergraduate students had severe or extremely severe depression. Kumar and Narayan (5) found that 56% of the students in their sample presented depressive symptoms (there was no difference between male and female students) and they seemed to decrease as students progressed through their years of study. Jose *et al.* (20) also found a high prevalence of depression (78.2% of the students had a depression score higher than 49), with women scoring higher than men. The authors also found a positive association between depression and insomnia. An even higher prevalence of depression was reported by Elavarasan *et al.* (21). A rate of 85.3% of the students in their study were suffering from depression and they found it to be related to internet addiction. More specifically, 95% of the participants who were addicted to the internet were found to be suffering from depression and students with internet addiction had four times the risk of being depressed when compared with those without internet addiction.

BRAZIL. Pacheco *et al.* (22), in a meta-analysis including 25 studies on depression among medical students in Brazil, found the prevalence to be 30.6% and positive associations with several variables: female gender; desire to switch courses; later stages of the course; internship cycle; clinical cycle; dissatisfaction with the course; tobacco smoking; average (compared to good) academic performance; difficulties in relationships; emotional tension; evening-type preference; feeling pressured by parents; having concerns about the future; not having a parent who was a physician; not participating in social activities; parents were physicians; poor or reasonable physical health; thoughts of dropping out; religion other than Catholic; sedentary lifestyle; sporadic or rare involvement in leisure activities; uncertainty about professional future.

BANGLADESH. Hossain and Wahab (23) reported that 40.8% of the students of Armed Forces Medical College, Dhaka Cantonment, had depressive symptoms (with no gender differences) and they were very significantly higher in their 1st year than 2nd, 3rd and 4th year. Also, depression was significantly higher in Non-English Medium background than English Medium background participants. Another Bangladeshi study (24) reported an even higher level of depression (46.3%). Also, depression symptoms represented a strong predictor for Facebook addiction.

AUSTRALIA. Said *et al.* (25) reported that 8% of the Australian medical students reported having depression and they identified the following groups as vulnerable: women, 25-34-year-old, students on low income, and homosexual or bisexual students.

ROMANIA. Symptoms of depression,

ranging from mild to severe, were also found among first-year nursing students in a medical University from Romania (26). The prevalence of depression symptoms was 20% and the authors also found significant statistical correlations between depression and a series of variables: age, experience as a nurse, emotional exhaustion, introversion, emotional instability and job satisfaction. In another Romanian study, this time centered on dental and psychotherapy students, there was a moderate association between professional stress and symptoms of depression (27). More specifically, there was a positive association between the level of stress related to professional identity, faculty administration, workload and depression.

Taking into consideration the fact that poor mental health begins in medical school, it is important to gain insight into health-relevant factors early on in order to further career development of medical students. Given the fact that data on health status of medical students in Romania is scarce, we aimed at gathering some data regarding depression, anxiety and stress among them. More specifically, we examined the prevalence of the variables and their relationship with sex, sleeping hours per night, BMI, tobacco, alcohol, coffee, carbonated drinks, energy drinks, ethnobotanicals and drug use.

MATERIAL AND METHODS

Participants

A number of 190 medical students from all years of study provided answers to an online questionnaire. The participants were informed about the purpose of the study, about the confidentiality of data and the use of results. The questionnaire consisted of two parts: the first one gathered socio-demographic information, while the second one is a psychological instrument measuring the levels of *depression, anxiety and stress - DASS 21*.

Socio-demographic data and psychological tool

Students had to provide socio-demographic (sex, age, year of study, environment, faculty, living arrangements), anthropometrical (height, weight) and medical data (chronic diseases). They also had to provide information concerning dietary (tobacco, alcohol, coffee, carbonated drinks, energy drinks and drugs consumption) and sleeping habits. Academic results and family situation (siblings, level of education for both parents and having at least one parent working abroad) were also recorded.

The Depression, Anxiety and Stress Scale (*DASS 21)* (28) is a self-report instrument designed to measure the emotional states of depression, anxiety and stress. Each of its three scales consists of 7 items. The depression scale assesses dysphoria, hopelessness, devaluation of life, self-deprecation, lack of interest / involvement, anhedonia and inertia. The anxiety scale assesses autonomic arousal, skeletal musculature effects, situational anxiety, and subjective experience of anxious affect. The stress scale assesses difficulty relaxing, nervous arousal, and being easily upset/agitated, irritable / over-reactive and impatient.

The present study employed the short version of the DASS (21 items) due to several advantages: fewer items, a cleaner factor structure, and smaller interfactor correlations (29).

Statistical analysis was performed using *SPSS Statistics version 21.0.* Means, standard deviations and percentages were used

for descriptive analysis. Comparative analysis was performed using Independent Samples *t-test* and *One-way ANOVA*. For correlational analyses we used *Pearson* and *Spearman* correlations.

RESULTS

Socio-demographic and health related data

The mean age for the sample is 21.38 (±2.18), with a majority of female participants (79.5%). Most of the students were enrolled in their third year of study (32.2%), followed by first (27%), second (23.8%), sixth year (7.4%), fourth (6.9%), and fifth year students (2.1%).

The majority of the participants were from urban areas (66.3%) and the vast majority was not married (95.8%). Most of the students (90.5%) declared no chronic disease.

Academic results and family situation

The baccalaureate mean for the sample is 9.04 (±.78) and the admission mean is 8.30 (±1.20). 42.1% of the students declared that one parent or both worked abroad. Almost half of them lived in dorm rooms or rental accommodation (48.4%). The rest of them lived with family (25.3%), life partner (13.7%) or alone (12.6%).

Anthropometric data, dietary and sleep habits

Mean weight for female students in our sample is 59.01 kg (±8.92), with a mean height of 165.02 cm (±14.89). Mean weight for male participants is 78.59 kg (±11.32), with a mean height of 181.15 cm (±6.76).

The body-mass index (BMI) for both genders was measured using self-declared data regarding weight and height. The values taken into consideration were WHO's standards for European population: a BMI < 18.5 kg/m^2 was categorized as underweight, 18.5-24.9 kg/m^2 as the normal range, 25.0-29.9 kg/m^2 as pre-obese, 30-34.9 kg/m^2 as obese class I, 35.0-39.9 kg/m^2 as obese class II and ≥ 40 kg/m^2 as obese Class III (30).

Most of the students have a normal BMI (73.4%), although we also identified underweight (11.2%), pre-obese (12.2%), and obese class I (3.2%) participants (tab. I).

TABLE I

BMI for men and women

Variables	Total results	Women	Men
Weight (kg)	63.03 ± 12.32	59.01 ± 8.92	78.59 ± 11.31
BMI	21.90 ± 3.21	21 ± 2.98	23.94 ± 3.31
Underweight	11.2%	13.4%	2.60%
Normal weight	73.4%	76.5%	61.5%
Pre-obese	12.2%	7.40%	30.8%
Obesity class I	3.20%	2.70%	5.10%

Table II presents students' smoking and drinking habits. More specifically, 16.3% of the subjects smoke on a daily basis, 11.6% of the students drink alcohol monthly or weekly, a high percentage (42.1%) declared they drank coffee every day, 51.1% occasionally drink carbonated drinks and 33.2% occasionally drink energy drinks. The majority of students claimed they never used ethnobotanicals (95.3%) or drugs (91.6%). A small percentage of participants used ethnobotanicals (4.7%) or drugs (7.9%), while the majority declared they never used them ((95.3%, 91.6% respectively).

TABLE II

The frequency of consumption (%)

Habit	never	occasionally	monthly	weekly	daily
Tobacco	60	18.9	.5	4.2	16.3
Alcohol	21.1	67.4	3.2	8.4	0
Coffee	14.7	30	3.7	9.5	42.1
Carbonated drinks	11.6	51.1	11.1	17.9	8.4
Energy drinks	58.4	33.2	2.6	2.1	3.7
Ethnobotanicals	95.3	4.7	0	0	0
Drugs	91.6	7.9	.5	0	0

Regarding sleeping hours, medical students reported a mean of 7.07 (±1.18) hours per night. Concerning the inquiry of whether they wake up during the night, the participants reported the following: *never* - 17.9%, *occasionally* - 68.4%, *monthly* - 1.1%, *weekly* - 4.2%, *every night* - 8.4%.

Depression, anxiety and stress

The results from the *DASS-21* show elevated levels of depression, anxiety, and stress among the students from our sample (tab. III). More specifically, more than a quarter of the participants reported moderate depression (28.9%), while 17.3% appear to have severe depression and 16.3% extremely severe depression. Concerning anxiety, 30.5% of the students present moderate symptoms, 9.5% severe symptoms, and almost a quarter (23.2%) of students suffer from extremely severe anxiety. In the case of stress, 26.3% of the participants in the sample reported levels ranging from moderate to extremely severe.

TABLE III

DASS 21 results

Level	Depression (%)	Anxiety (%)	Stress (%)
Normal	25.3	27.4	60.5
Mild	12.1	9.5	13.2
Moderate	28.9	30.5	11.6
Severe	17.4	9.5	10.0
Extremely severe	16.3	23.2	4.7

Correlation analysis

In order to identify the existing relationship between the *DASS-21* scales and the number of sleeping hours per night and BMI, Pearson correlation were performed. The results showed significant negative correlations between the three scales of the *DASS-21* and the hours students sleep per night: depression ($r = -.253$, $p < .001$), anxiety ($r = -.210$, $p = .004$), and stress ($r = -.249$, $p = .001$). More specifically, the more students sleep, the lower they score on depression, anxiety, and stress; conversely, the less they sleep, the higher they score on all scales of the DASS-21. In the case of BMI, there is no association between this variable and the scales of the *DASS-21*.

Spearman correlations were performed in order to establish the relationship between the three scales of the DASS-21 and tobacco, alcohol, coffee, carbonated drinks, energy drinks, ethno-botanicals and drug use. The results showed positive and significant

associations between depression and alcohol (r = .155, p = .03) and carbonated drinks consumption (r = .146, p = .04), meaning that students who rate themselves as consuming alcohol and carbonated drinks more frequently also score higher on depression.

Comparative analysis

Independent samples t tests showed statistically significant differences between male (N = 39) and female (N = 151) participants concerning depression (t(88) = 4.40, p < .001), anxiety (t(88) = 4.25, p < .001) and stress (t(88) = 4.70, p < .001). More specifically, women scored higher than men on all subscales of the DASS-21: depression (Mwomen = 18.58, Mmen = 10.92), anxiety (Mwomen = 14.95, Mmen = 7.94) and stress (Mwomen = 15.37, Mmen = 7.48).

One-Way ANOVA showed statistically significant differences in stress according to participants' BMI (F(184) = 3.81, p = .01). More specifically, participants with normal weight have lower scores (M = 13.11) than pre-obese (M=13.13) and obese class I participants (M=26.33). Concerning anxiety and depression, *One-Way ANOVA* analyses showed no statistically significant differences between participants according to their BMI.

DISCUSSION

Medical studies are characterized by the longest period invested in academic study, a continuously preparation for theoretical and practical achievement and require commitment, determination and responsibility. Students enrolled in medical faculties are under high stress due to high academic load, long working hours, new living accommodation, financial strain etc. The mental health of medical students worsens after they begin their studies and remains unsatisfactory all throughout training. More specifically, studies show high prevalence of depression among medical students from their first years of study to their last and even after completion (31). Also, studies report that medical students suffer from depression, anxiety, and stress. Yusoff *et al.* reported that healthy students develop depression and stress after commencing their medical education (32-34).

Our results reveled high rates of depression, anxiety and stress among female medical students and they tend to score higher than on these dimensions. These results are congruent with other research. For example, Brenneisen Mayer *et al.* (35) found a 41% prevalence of depression among medical students, with more depressive symptoms among female students and students from schools located in capital cities. Also, higher scores of depression, anxiety and stress were reported in students with the following characteristics: females, in lower semesters, younger and nonsmokers. Furthermore, students who were satisfied with their education had lower depression, anxiety and stress scores (19). Bore *et al.* (36) also found that female students in their sample were significantly more depressed compared to the female norms, while male depression did not differ from male norms. Another study conducted by Moutinho *et al.* (4) revealed a prevalence of 34.6% in medical students from all semesters of a Brazilian medical school. Assessing associated factors for depression, they found the following: female gender, intrinsic religiosity, anxiety, and stress. Also, Ibrahim and Abdelreheem (37) found a high prevalence of depression (57.9%), with a higher prevalence among female students. Also, medical students presented higher rates of depression compared to pharmaceutical students.

However, some other studies revealed no difference in depression considering gender as variable. Sharma *et al.* (31) reported that 31% of the students in their sample (private university) had depression (there were no gender differences) and it was higher in the first year compared to 3rd and 4th but increased after the completion of studies and the beginning of internship. They also found a significant association of depression with regularity of attendance the courses.

Also, some studies indicated the existence of a relationship between the DASS dimensions and the consumption of alcohol, tobacco and drugs (19). The present research showed that there are positive and significant associations between depression and alcohol ($r = .155$, $p = .03$) and carbonated drinks consumption ($r = .146$, $p = .04$), meaning that students who rate themselves as consuming alcohol and carbonated drinks more frequently also score higher on depression.

Sleep disorders are a real problem among medical students. One explanation could be that the university schedule is forcing them to mix theoretical and practical sessions with a hard investment of time for learning. Compared to general population scores, medical students sleep less and have more sleep-related problems. This is probably due to several reasons: the long duration of the academic achievement, demanding clinical study, a lot of practical duties that include overnight on-call activities, a hard work that can be emotionally challenging (increasing the level of burnout), a high level of consummation of energy drinks, coffee or dietary supplements, and, not to be neglected, their lifestyle choices (38). Also, sleep is closely related to good physical and psychological health and academic performance (39-41). The present study also found that sleeping hours have an impact on mental health. Specifically, the more students sleep, the lower they score on depression, anxiety, and stress; conversely, the less they sleep, the higher they score on all scales of the psychological instrument used for this research.

There is a great need for the promotion of mental health, given the fact that medical students present high rates of depression, with a focus on vulnerable groups: female students, students with financial difficulties, students with various addictions etc. Also, mental health professionals should focus on depression stigma (13) and should also address the fact that neither students nor healthcare professionals are inclined to seek help when they have mental health problems (8-10).

Our study showed that there is a statistically significant differences in stress according to participants' BMI (normal weight students having lower scores on stress comparing to over-weight students), but not when considering depression or anxiety.

CONCLUSIONS

High rates of depression, anxiety and stress are recorded among medical students. Increased rates of alcohol consumption, sleep-related problems, high body mass-index are found to be factors influencing students' levels of stress, anxiety and depression. Among them, females are more prone to experience these health problems. University teachers should include in their curricula topics aimed at preventing these psychological problems (in case they are related to lectures or clinical stages) or to arrange schedules in order to offer students more free time and proper sleep.

TENDINŢE ALE EVOLUŢIEI EPIDEMIOLOGICE A HEPATITELOR ACUTE VIRALE B ŞI C LA COPIL, ÎN ROMÂNIA ŞI JUDEŢUL IAŞI, ÎN PERIOADA 1990-2009

TRENDS IN EPIDEMIOLOGICAL EVOLUTION OF CHILD VIRAL HEPATITIS B AND C IN ROMANIA AND IAŞI COUNTY BETWEEN 1990 - 2009 (Abstract): Hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are the frequent causes of acute and chronic hepatitis worldwide and the leading causes for hepatic cirrhosis and liver cancer. There is a distinct geographical variation in VHB and VHC incidence in adult and child. **Aim**: To assess the evolution trend of VHB and VHC incidence in child, in Romania and Iasi County, during the last two decades. **Material and methods**: Data were obtained using information from the Reporting National System for acute viral hepatitis A, B, and C, from various geographical areas of Romania. Some systematical errors of information were identified, without significant influence of results and conclusions. **Results**: Results highlighted an incidence peak of VHB in Romania, in 1989, and in Iaşi county, in 1991 (43.1, respectively 41.2‰ inhabitants). The VHB incidence trend decreased after the implementation of vaccination programme, especially in children <4 years old. **Conclusions**: The study remarked the necessity of viral hepatitis surveillance programme continuity in Romania and the importance of prevention measures including, for VHB, an optimal vaccination. **Key words**: VIRAL HEPATITIS B, VIRAL HEPATITIS C, CHILD, VACCINATION PROGRAMME

Infecţia cu virusurile hepatitelor B şi C la copil se caracterizează prin unele aspecte epidemiologice şi clinice particulare. Riscul cronicizării este invers corelat cu vârsta producerii infecţiei, iar în cazul hepatitei virale B (HVB), poate să se situeze la 90% dintre copiii infectaţi în perioada de nounăscut, comparativ cu adulţii imunocompetenţi, care pot croniciza în 5% din cazuri. Dintre purtătorii cronici de virus, 15-20% pot dezvolta ciroză sau hepatocarcinom (1). Introducerea, în anul 1995, şi în România, a vaccinării anti-virus hepatitic B (VHB), în Programul Naţional de Imunizare, a schimbat, în mod semnificativ, evoluţia acestei infecţii în populaţia generală şi la grupurile cu risc, ceea ce se reflectă şi în tendinţa de reducere a incidenţei bolii, mai ales la copii (2).

Hepatita virală C (HVC) rămâne o provocare atât pentru patologia pediatrică, cât şi a adultului tânăr, iar consecinţele bolii, reflectate în nivelul de calitate a vieţii şi creşterea costurilor pentru asigurarea îngrijirilor sau a terapiei, face cu atât mai necesară aplicarea strategiilor de control şi de prevenţie generală a bolii, în absenţa vaccinării (3,4).

Studiul îşi propune să evalueze tendinţa în evoluţia incidenţei HVB şi HVC, la copil, în România şi particularizat pentru judeţul Iaşi, în perioada 1990-2009, perioadă ana-

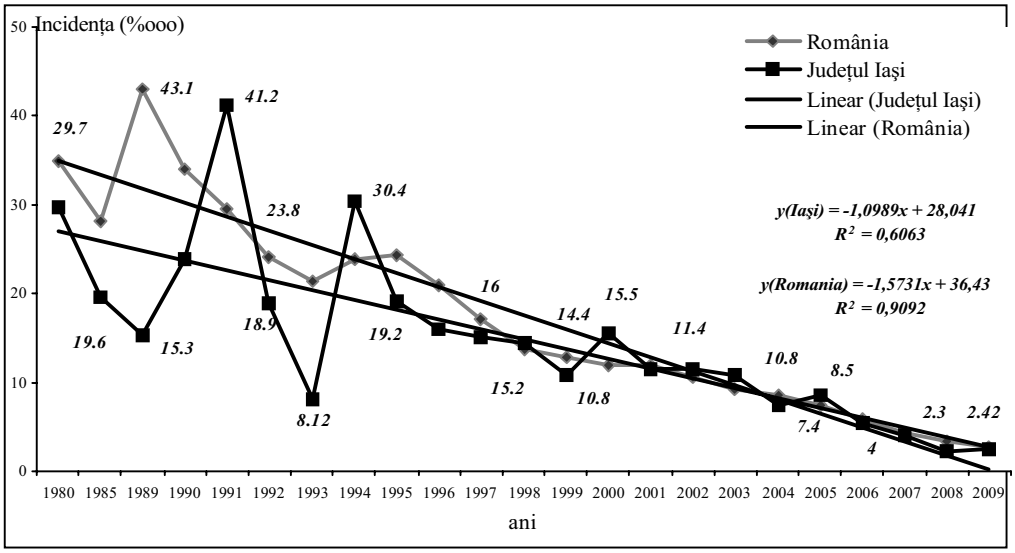

Fig. 1. Incidenţa hepatitei virale B, în România şi judeţul Iaşi, în perioada 1980-2009

lizată şi în relaţie cu momentul introducerii vaccinării anti-VHB, în Programul Naţional de Imunizare.

MATERIAL ŞI METODE

Datele incluse în studiu au fost obţinute prin Sistemul Naţional de Raportare a hepatitelor virale (HV), iniţiat încă din 1978, iar cele privind cazurile noi pe tipuri de hepatită, regiune, grupuri de vârstă şi rezidenţă au fost obţinute de la Centrul Naţional pentru Organizarea şi Asigurarea Sistemului Informaţional şi Informatic în Domeniul Sănătăţii din cadrul Ministerului Sănătăţii Publice (5). În desfăşurarea studiului, am identificat riscul producerii unor erori de informare prin utilizarea, în sistemul de raportare, a termenului de *hepatită nonA nonB* care reuneşte cazurile de boală hepatică acută virală infirmate, cu ajutorul examenelor de laborator, ca fiind cauzate de virusul A sau B şi încadrate în categoria HVC. În perioada 1990-2009, pentru toate cazurile de hepatită nonAnon B, diagnosticul de HVC a fost validat inclusiv prin dozarea anticorpilor anti-VHC.

Pentru analiza datelor înregistrate la copil, prin Sistemul Naţional de Raportare, în perioada de studiu la care ne referim, s-a remarcat o dificultate ca urmare a schimbării în raportare a structurării grupurilor de vârstă, ceea ce a determinat o analiză pe etape a fenomenului cercetat.

REZULTATE

*1. Evoluţia hepatitelor acute virale B şi C, în populaţia generală din România şi judeţul Iasi în perioada 1990-2009***.** Din datele de incidenţă înregistrate la nivel naţional, pentru toate grupurile de vârstă, se remarcă nivelul crescut al HVB în deceniile 8 şi 9 (43,1 şi 24,4‰ loc. în 1989, respectiv 1995), pentru ca, în ultimii 9 ani, numărul cazurilor să scadă semnificativ la 6,1 în anul 2000 şi 2,42‰ în 2009 (fig. 1).

Incidenţa HVC în România s-a încadrat între valorile cele mai scăzute de 0,8 şi 1,3‰ în 1980, respectiv 1989 şi cele mai crescute de 7,6 ‰ în 2001. Pentru judeţul Iaşi, incidenţa urmează tendinţa înregistrată în întreaga ţară, cu excepţia anului 1998 când au fost raportate valori

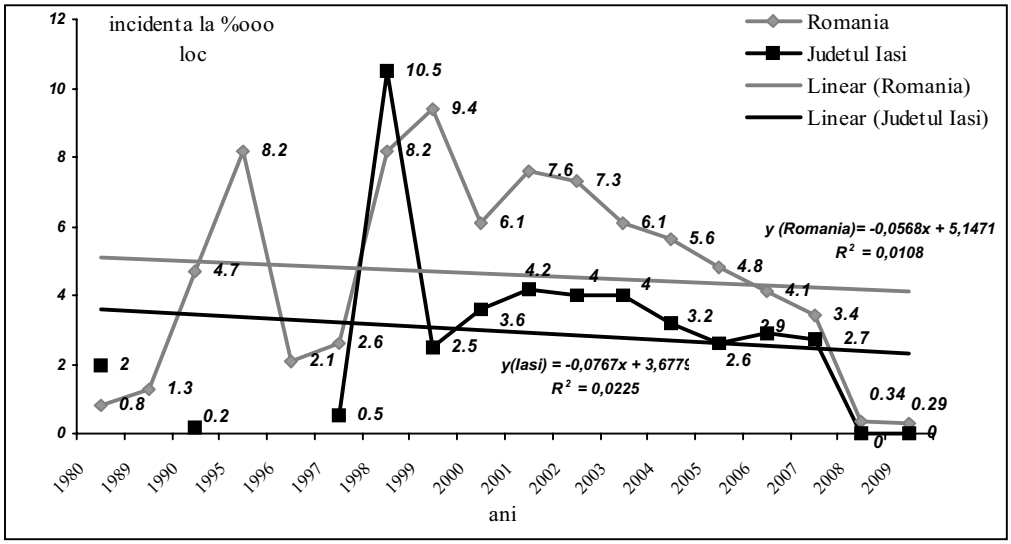

Fig. 2. Incidenţa hepatitei virale C, în România, în perioada 1980-2009

de 10,5%ooo, comparativ cu România, de 8,2%ooo.

2. Evoluţia hepatitei acute virale B şi C la copil, în România şi Judeţul Iaşi, în perioada 1990-2009. Scăderea numărului de cazuri de HVB la copil, în România, atât la grupul de vârstă <1 an, cât şi la 1-14 ani, a fost semnificativ influenţata de schimbarea politicii de vaccinare, începând cu 1995 (tab. I).

După un interval de 5 ani de la introducerea vaccinării anti-VHB, în Programul Naţional de Imunizare, cele mai multe cazuri au fost înregistrate la grupurile de vârstă 5-9, respectiv 10-14 ani, ceea ce demonstrează că imunizarea a avut un impact pozitiv în protecţia specifică a copiilor din România şi respectiv din Judeţul Iaşi (tab. II, fig. 3).

În judeţul Iaşi, situaţia înregistrată după anul 2000 (la 5 ani de la introducerea vaccinării), a fost similară cu cea înregistrată în întreaga ţară, fiind justificată de raportarea celor mai multe cazuri la copiii din grupurile de vârstă 5-9, respectiv 10-14 ani.

Pentru HVC, numărul de cazuri raportate la copii cu vârsta de 1-14 ani a fost redus atât la nivelul României, cât şi al judeţului Iaşi. Cazurile au fost înregistrate la diverse vârste din intervalul 1-14 ani (tab. III, fig. 4).

DISCUŢII

Incidenţa HVB şi HVC în ţările din Uniunea Europeană variază în funcţie de zona geografică, având o tendinţă comună de scădere pentru HVB şi de creştere pentru HVC. Prevalenţa purtătorilor de VHB s-a încadrat în intervalul 0,1-8,0% (6% valoarea raportată pentru România) şi 0,1-6,0% pentru VHC (6,7,8). În România, evoluţia HVB, în perioada anterioară introducerii vaccinării anti-VHB, a fost marcată de un nivel al incidenţei bolii ridicat, mai ales la copil.

Studiile efectuate în România (2,8,9,10, 11,12,13,14), în diverse zone geografice, relevă caracterul de endemicitate a HVB cu tendinţă de scădere a numărului cazurilor noi de boală, la copii, ceea ce constituie dovada eficienţei tuturor măsurilor preventionale, aplicate după anii '90: folosirea seringilor de unică utilizare în activităţile

ultima clasă de liceu (2004) (2).

Vaccinarea efectuată în mod sistematic, cu 3 doze după schema 0-2-6 luni de viaţă, la nou-născut sau la un interval de 0-1-6 luni la alte grupuri de vârstă (copiii de 9 ani neimunizaţi la naştere), cu întreruperi accidentale cauzate de lipsa preparatului vaccinal, a generat o acoperire vaccinală, prin titruri protective de anticorpi specifici anti-VHB, de peste 95% (2) şi respectiv la nou-născut de 99,9% în anii 1997 şi 1998, de 98,0% în 1999, în 2000 de 99,0 % şi 98,0% în 2001 (15). Cazurile raportate după 1995, au fost înregistrate preponderent la copiii născuţi înainte de 1995 (grupurile de vârstă de peste 1 an), sporadic la copiii rămaşi nevaccinaţi sau la cei vaccinaţi, la care răspunsul imun post-vaccinare a fost sub nivelul protector.

În judeţul Iasi, incidenţa HVB a fost sub valoarea înregistrată la nivel naţional, cu excepţia anilor 1991, 1994 şi 2000. La copii, imunizarea corect aplicată şi monitorizată a dus la scăderea importantă a incidenţei cazurilor. Strategia actuală, la nivelul judeţului Iasi, este de menţinerea acestei

TABELUL III
Numărul de cazuri noi de hepatită virală C raportate la copii, în România, în perioada 1999-2009

Anul / Grupuri de vârstă (ani)	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009

situaţii favorabile privind incidenţa HVB şi, mai ales, evitarea golurilor de imunizare.

În cazul infecţiei cu VHC, chiar în situaţia subraportării posibile, datorită formelor clinice asimptomatice nedepistate sau a dificultăţilor de confirmare a diagnosticului prin examenul de laborator, în perioada 1995--2005, au fost raportate 250.000 de cazuri de HVC în 24 ţări ale UE. Prevalenţa infecţiei cu VHC a variat în intervalul de 0,1--6,0%, România fiind inclusă în categoria ţărilor cu nivelul cel mai înalt, de 6% (16).

Incidenţa HVC pediatrică în România, cu excepţia anului 1999, când au fost raportate 19 cazuri la copiii < 1 an la nivelul întregii ţări şi respectiv 21 cazuri în anul 1998, înregistrate la grupul de vârstă 1-4 ani, în judeţul Iaşi, a avut un nivel scăzut. Explicaţia pentru nivelul redus al incidenţei la copil poate consta în specificitatea transmiterii virusului, mai puţin frecvent de la mamă la copil, precum şi ca rezultat al măsurilor de prevenţie şi control, care au fost aplicate pentru toate infecţiile produse de virusurile cu transmitere prin sânge, derivatele sale sau alte produse biologice provenite de la bolnavi sau purtători.

Hepatita virală C la copil, în judeţul Iaşi, nu pare a pune probleme dacă am analiza fenomenul numai prin evaluarea incidenţei cazurilor. Privind aceste cazuri diagnosticate ca fiind un posibil vârf al „iceberg-ului" şi apreciind ca dificilă îngrijirea şi aplicarea terapiei adecvate la cazurile depistate, considerăm că această infecţie trebuie să rămână în atenţia medicilor pediatri şi a tuturor specialiştilor (infecţionişti, virusologi, epidemiologi etc.) care contribuie la ţinerea sub control a fenomenului.

CONCLUZII

România care face parte, de mai mulţi ani, din reţelele europene de supraveghere a hepatitelor virale,beneficiază de un sistem de supraveghere de tip pasiv, bazat, mai ales, pe raportarea cazurilor acute. Studiile de morbiditate şi de seroprevalenţă, efectuate în ultimele două decenii, au completat golurile informaţionale privind această patologie, la diversele grupuri de vârstă (sau de risc), inclusiv la copil. În România, se menţine caracterul de endemicitate pentru HVB şi HVC, fiind remarcată scăderea semnificativă a incidenţei HVB, semnificativ la copil, după aplicarea strategiei de imunizare, prin introducerea vaccinării anti-VHB, încă de la naştere sau, ulterior, la vârsta adolescenţei.

Cazurile apărute la copil, după 1995, pot avea mai multe cauze care pot fi stabilite pe baza evaluărilor analitice ale factorilor de risc, identificaţi prin anchetele epidemiologice. Demonstrarea existenţei unor goluri imunitare, în populaţia infantilă, ca urmare a unor factori individuali, de răspuns la preparatul vaccinal, de infecţie cu anumite genotipuri de VHB sau ca urmare a unor disfuncţionalităţi tehnice de administrare a vaccinului, poate constitui un subiect particular, care să fie analizat în vederea optimizării sistemului de prevenţie a infecţiilor cu VH în România.

Continuarea strategiei de supraveghere a infecţiei cu VHB, după standardele europene, precum şi menţinerea unei acoperiri vaccinale optime, ca urmare a aplicării programului de imunizare adecvat situaţiei epidemiologice din România, constituie o speranţă în ţinerea sub control a acestei infecţii şi, mai ales, de reducere a consecinţelor legate de povara bolii, la copil.

Hepatita virală C, încă subestimată, ca urmare a limitelor de depistare şi diagnostic, înregistrează niveluri în creştere, dar semnificativ mult reduse faţă de HVB. Pentru România, chiar dacă, în ultimii ani, numărul de cazuri noi de boală, la copil, a fost redus, iar posibilitatea transmiterii mult diminuată prin măsurile preventionale, o supraveghere continuă a infecţiei este necesară, mai ales în contextul în care perspectiva protecţiei specifice prin vaccinare este mult îndepărtată, iar posibilităţile actuale de monitorizare şi terapie a cazurilor, limitate.

ADNEXAL MASSES IN PREGNANCY: A TWO-CENTER EXPERIENCE (Abstract): **Aim**: To evaluate the characteristics of adnexal masses in pregnancy diagnosed and managed in our centers. **Material and methods**: This study was conducted in the interval January 2008-December 2017 in two major centers. Included in the study were pregnant women diagnosed with adnexal masses detected by ultrasound or incidentally during cesarean delivery. Adnexal masses were evaluated ultrasonically and histopathologicaly. **Results:** The incidence of adnexal masses in pregnancy identified in our study was 0.31 %. Prenatal diagnosis of adnexal masses was made in 140 cases (66.6 %), 70 cases (33.3 %) being diagnosed during cesarean section. The mean size of all adnexal masses was 6.8 cm. Histopathologically, the vast majority of adnexal masses were benign tumors. The most common complication of adnexal masses during pregnancy was ovarian torsion. **Conclusions:** It is very important to know that adnexal masses can progress rapidly and can be life-threatening for the mother and fetus; thus it is absolutely necessary to develop and implement specific diagnostic and treatment protocols. **Keywords:** ANNEXAL MASSES, PREGNANCY, ULTRASONOGRAPHY.

Adnexal masses have become increasingly common in daily obstetric practice, representing a diagnostic and therapeutic challenge for the physician, especially in the absence of specific management protocols. The precise incidence of adnexal masses in pregnancy is unknown and varies widely, being variably reported as 0.15-5.7% (1-3). It is clear that due to repeated ultrasound examinations specific to pregnancy monitoring protocols, the diagnosis of adnexal masses in the early stages of gestation has increased, many of them being asymptomatic (4). In some situations, the presence of these masses is an unexpected intraoperative finding, given the increasing cesarean delivery rate. Adnexal masses can be found in pregnant women of any age. They have their origin in the ovaries, fallopian tubes, or surrounding tissue and are characterized by high clinical, laboratory and histological variability (5). The majority of adnexal masses in pregnancy are benign, and the incidence of malignancy is approximately 6% (2). It is very important to know that the progression

of adnexal masses can be fast and life-threatening for both the mother and fetus, being identified in any trimester of pregnancy, and the therapeutic approach must take into account the gestational age and maternofetal status. Also, during pregnancy, surgical management of adnexal masses and their complications is more difficult and more challenging (1). In this context, the aim of this retrospective study is to evaluate the characteristics of adnexal masses in pregnancy, diagnosed and managed in two centers.

MATERIAL AND METHOD

This study was conducted in the interval January 2008 - December 2017 in two centers: "Cuza-Vodă" University Hospital, Iași, Romania, a tertiary referral obstetrics and gynecology center and "Elena-Doamna" University Hospital Iași, Romania. The medical records of pregnant women were reviewed retrospectively using the specific codes of the World Health Organization (WHO) - International Classification of Diseases (ICD): C56, C57.0, C 57.1, C57.2, C57.3, C57.4, D27, D39.1, N83.0, N83.1, N83.2, N83.5, N83.9. The inclusion criterion was represented by pregnant women diagnosed with adnexal masses at ultrasound examination or detected incidentally during cesarean delivery. Eligible women were identified by the research coordinator and/or the medical staff involved in project. Data on patients' clinical course and their operative records were collected from the hospital computerized database. The following parameters were evaluated: maternal age and parity, clinical presentations, ultrasound features of the detected masses and gestational age at diagnosis, adnexal mass-associated complications, gestational age at the time of surgery, and histopathological diagnosis of adnexal masses. Prenatal screening in these cases was performed according to specific protocols by blood tests and ultrasound: dating / viability at 7-9 weeks, first trimester screening between 11-14 weeks, scan for fetal anomalies between 19-22 weeks and fetal wellbeing ultrasound in the third trimester. Adnexal masses were ultrasonically evaluated whenever necessary in our centers (transvaginal ultrasound) in terms of tumor size and location, morphological and vascular features. The differential diagnosis included malignant ovarian tumors (borderline tumors included), and in the cases requiring surgery the extemporaneous examination and the final histopathological report. These patients were treated by classical laparotomy, the main indications for surgery being symptomatic adnexal mass (adnexal torsion), enlarging mass, or suspicion of malignancy. Exclusion criteria were non-gynecologic pelvic masses, pregnancies of unknown or ectopic location, and ovarian stimulation treatment. *Statistical analysis* was performed using SPSS version 17.0 software. Data were expressed as mean ± SD. Mean, standard error of the mean, and standard deviation were determined for quantitative variables. Categorical variables were expressed as number and percentage (%) of patients. The study was approved by the local Ethics Committee (No:790/25.01.2017) and conducted in accordance with the Helsinki Declaration.

RESULTS

Between January 2008 and December 2017 at the Iasi "Cuza-Vodă" University Hospital and "Elena-Doamna" University Hospital, 70,779 births were recorded, of which 226 (0.31 %) were diagnosed with

adnexal masses in pregnancy. Of all these patient, only for 210 cases we were able to collect all data required for a complete statistical processing. The mean age of the patients at the time of adnexal mass detection was 28 years +/- 5.18 years (mean +/- SD) and the mean biometric age was 33 weeks of amenorrhea +/- 10.19 weeks (mean +/- SD). A hundred and thirty-six patients were primipara (64.7 %), and 74 patients were multipara (35.2%). In the study group, 13 patients (6.1 %) had spontaneous abortions (before 20 weeks of gestation, none after surgery for complication of adnexal masses), 77 patients (36.6%) had cesarean (C-section). Prenatal diagnosis of adnexal masses was made in 140 cases (66.6 %), 70 cases (33.3 %) being diagnosed during C- section. Only three patients (1.4 %) underwent surgery during the antepartum period: two in the first trimester (at 7 and 9 weeks of gestation, respectively) and one in second trimester at 14 weeks of gestation. In 66 cases (31.4 %) adnexal mass surgery was performed at the same time as the C-section. The masses were detected on the right side in 84 cases (40 %), on the left side in 124 cases (59 %), and bilaterally in 2 cases (fig. 1). The mean size of all adnexal masses was 6.8 cm.

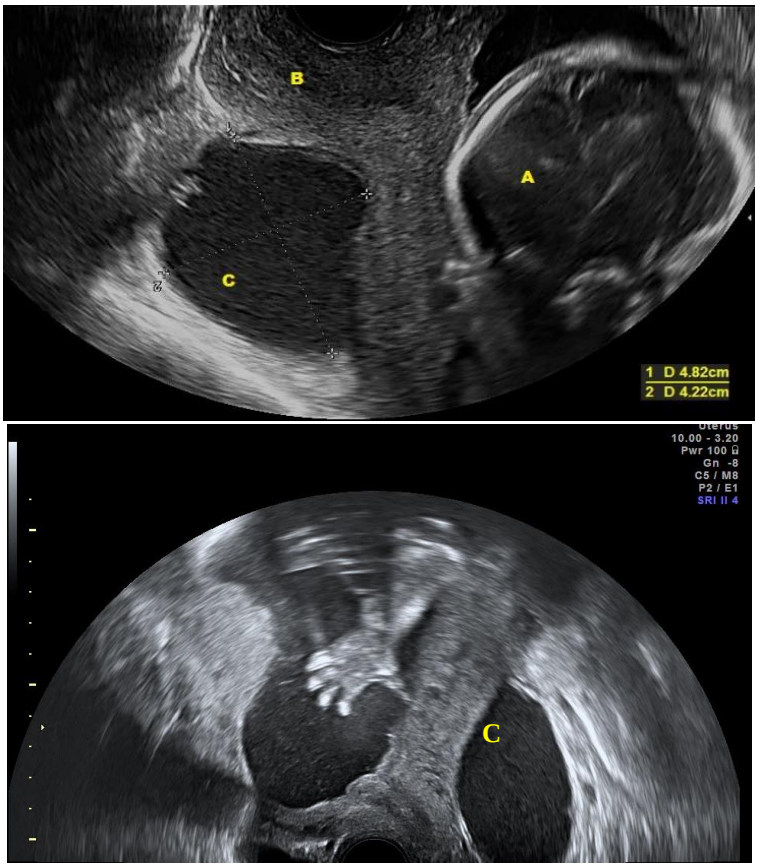

Fig. 1. 26-year-old pregnant woman- a transvaginal ultrasound obtained at 18 weeks' of gestation: A. fetal head; B. cervix; C. adnexal mass-ovarian cyst

The clinical manifestations of adnexal masses were dominated by nonspecific diffuse abdominal pain. The most common complication of adnexal masses during pregnancy was ovarian torsion- 6 cases (2.85 %, 4 in the first trimester and 2 in the second trimester- who needed emergency surgery), followed by hysterectomy in 3 cases of ovarian cancer confirmed by histopathological extemporaneous examination. Pathology results and surgical procedures used in the management of adnexal masses are presented in Table I. In 2 cases, the ovarian cysts were removed by transabdominal puncture and aspiration at 13 weeks and 32 weeks of gestation.

TABLE I

Pathology results and clinical characteristics of adnexal masses in surgically managed patients

Sr. No.	Pathology	No. (% of all cases)	Clinical manifestation (No. cases)	Mean size (cm)	Surgical procedure (No. cases)
1	Serous cystadenoma	23 (10.9%)	asymptomatic (13) symptomatic (10)	10.5	salpingo-oophorectomy (13) cystectomy (8) release of torsion (2)
2	Functional ovarian cyst	12 (5.7%)	asymptomatic (10) symptomatic (2)	6.5	salpingo-oophorectomy (6) cystectomy (6)
3	Para tubal cyst	10 4.7%)	asymptomatic (9) symptomatic (1)	6	cystectomy (8) salpingectomy (2)
4	Endometrioma	10 (4.7%)	asymptomatic (7) symptomatic (3)	6.5	cystectomy (10)
5	Dermoid Cyst	8 (3.8%)	asymptomatic (7) symptomatic (1)	5.8	salpingo-oophorectomy (2) cystectomy (6)
6	Cystadenocarcinoma (including borderline tumor)	3 (1.4%)	asymptomatic (3)	6.7	Hysterectomy with bilateral salpingo-oophorectomy (3)
7	Hemorrhagic cyst	3 (1.4%)	symptomatic (3)	6.2	salpingo-oophorectomy (2) cystectomy (1)

DISCUSSION

The incidence of adnexal masses in pregnancy identified in our study was 0.31 %, which is in agreement with the incidence reported by most authors. Although the vast majority of adnexal masses are diagnosed by ultrasound in the first trimester (21.4–75.7% of cases) (6), in our case the advanced gestational age at the time of diagnosis (33 weeks) can be explained by the absence of specific monitoring of pregnancy. Many of these patients are of low socioeconomic status without immediate access to specialized prenatal care. Also, although we have identified a spontaneous abortion rate of 6.1 %, it is difficult to say that this is entirely due to the presence of adnexal masses, which may however be associated with a poor obstetric outcome, depending on their size and location (6). Only 16% of

cases were diagnosed in the first trimester of pregnancy. Analyzing the databases, it is evident that in some studies the specialists opt for a conservative attitude of observing the progression of adnexal masses, whereas in others, elective surgeries in the first and second trimester are preferred (7). In our study, in the vast majority of cases we opted for a conservative approach of adnexal masses. This option was based on the finding that the vast majority of ovarian cystic masses identified in the first trimester of pregnancy, disappear later (8,9). A very important role in the monitoring of adnexal cystic masses and the identification of suspected malignancies is played by ultrasound examination, analyzing such specific aspects as: size, septations, internal cyst walls, acoustic shadows, bilaterally of masses, irregular unilocular/multilocular tumor, ascites, papillary structures and increased vascularity as determined by Doppler ultrasound- International Ovarian Tumor Analysis (IOTA) rules to diagnose ovarian cancer (10). In this context it is very important to remember that IOTA simple rules can be used to classify 75% of all adnexal masses as benign or malignant. However, it should be noted that evaluating the ultrasound characteristics of adnexal masses in the third trimester of pregnancy can be difficult.

Ultrasonography is the primary imaging modality used to assess adnexal masses, but in some cases the findings may be nonspecific and it is MRI (Magnetic Resonance Imaging) that can provide new data regarding the diagnosis (7). Although in some of our cases MRI was performed, we were unable to obtain adequate data for a more detailed analysis. The measurement of serum tumor marker CA-125 was not included in the differential diagnosis of adnexal masses due in particular to its lack of specificity and high levels in pregnancy, which can lead to false positive results for the risk of malignancy (4). Levels of other markers, such as alpha-fetoprotein (AFP), human chorionic gonadotropin and lactate dehydrogenase can be elevated during pregnancy normally or as a result of abnormal placentation or fetal anomaly (12). The malignancy rate of adnexal masses was 1.4 %, which is comparable with the reported rates of 2% to 6% (1). It should be noted that Doppler evaluation of potentially malignant adnexal masses in pregnancy is difficult due to the fact that the vessels and blood flow surrounding the gravid uterus mainly have high velocity and low resistance characteristics (13). From the histopathological point of view, the vast majority of adnexal masses were benign tumors, respectively cystadenomas /functional ovarian cyst, which is in agreement with the data provided by other authors (14). Unlike functional cysts that are hormonally influenced and may disappear in pregnancy, cystadenomas are not hormonally sensitive and do not resolve after 16 weeks of pregnancy (15). Although most of the adnexal masses are asymptomatic, we have identified 6 cases of adnexal torsion (patients presenting severe pelvic pain, nausea, vomiting), which corresponds to the frequency reported by most authors. Most cases of torsion were diagnosed in the first trimester of pregnancy, especially on the right side, which is in accordance with other reports in showing that this complication mainly occurs during the first trimester of pregnancy when adnexal mass is larger than 5 cm (16). In general, starting with the second trimester of pregnancy, the incidence of the adnexal torsion is lower due to the increase in size of the gravid uterus. In 2 cases, surgery was performed for the suspicion of appendicitis, subsequently adnexal torsion being identified. Moreover, due to the nonspecific pain symptomatolo-

gy in pregnancy, adnexal torsion is difficult to differentiate from appendicitis and other diseases such as pyelonephritis and renal lithiasis (17). Regarding the therapeutic management of adnexal masses in pregnancy, the main problem is the lack of a specific protocol and a general consensus. In this context, although the surgical technique used differs, the vast majority of practicing specialists prefer laparoscopy. In our study we used laparotomic surgery in the management of adnexal masses, mainly due to the fact that the vast majority of adnexal masses were operated during cesarean section. Also, the inexperienced surgeons as well as the technical difficulties associated with laparoscopic interventions in pregnancy can be taken into consideration. The laparoscopic removal of adnexal masses in the first trimester of pregnancy is generally avoided, due in particular to the risk of miscarriage. However, there were no significant differences in the risk of miscarriage between women who underwent laparoscopy and those who underwent laparotomy. In the second trimester of pregnancy laparoscopic surgery may represent a technical challenge due to the complications associated with the use of the Veress needle or trocar (injury of the gravid uterus) and lack of visibility because of the limited space between the laparoscope and the adnexal mass (2). Transabdominal puncture and aspiration of ovarian cysts (performed in 2 study cases) is only indicated if they cause pain or obstruct labor (18).

CONCLUSIONS

The presence of adnexal masses in pregnancy can be a cause of anxiety for both the patient and the specialist. Although the vast majority of them disappear spontaneously in pregnancy, some of them may develop complications that may affect the maternal-fetal prognosis. In this context, it is absolutely necessary to develop and implement specific diagnostic and treatment protocols.

NEWS

VEOLIZUMAB – A CHALLENGE IN THE TREATMENT OF CROHN'S DISEASE

Vedolizumab is a humanized monoclonal antibody against α4β7 integrin, which prevents mucosal addressin cell adhesion molecule-1-mediated lymphocyte homing to the gut. It is effective as induction and maintenance therapy for patients with moderate to severe Crohn's disease (CD) and ulcerative colitis (UC).This was a prospective observational study of consecutive inflammatory bowel disease (IBD) patients who started vedolizumab treatment at a single tertiary referral center between May 2016 and June 2017. The main new finding of the study is the predictive value of induction and early maintenance vedolizumab trough levels for robust combined endoscopic and clinical remission by the end of the first year of vedolizumab treatment. An important finding of the study was the 96% negative predictive value of the vedolizumab trough level threshold of 17 mg/mL at week 6 for combined endoscopic and clinical remission. Trough levels below this threshold were observed in a high proportion of the patients. Early therapeutic drug monitoring could help identify patients at risk of unfavorable outcomes and provide an early opportunity for therapeutic intervention. This prospective real-life observational study with centrally evaluated endoscopy identified vedolizumab trough levels at week 6 to be a predictor of combined endoscopic and clinical remission, as defined by the Selecting Therapeutic Targets in Inflammatory Bowel Disease (STRIDE) programme. Taken together with the findings of others, trough levels at week 6 appear to be a promising tool to assist clinical decisions. The hypothesis-generating study warrants further research to explore whether patients with a low likelihood of combined remission (i.e. those with week 6 trough levels<17 mg/mL) could benefit from early dosing interval shortening, possibly including other relevant patient-reported outcomes (Hanzel J, Sever N, Ferkolj I, *et al*. Early vedolizumab trough levels predict combined endoscopic and clinical remission in inflammatory bowel disease. *United European Gastroenterol J.* 2019; 7(6): 741-749).

THE SIGNIFICANCE OF NEUTROPHIL TO LYMPHOCYTE RATIO, PLATELET TO LYMPHOCYTE RATIO AND LYMPHOCYTE TO MONOCYTE RATIO IN PERIPHERAL BLOOD OF PATIENTS WITH BENIGN AND MALIGNANT ORAL LESIONS

THE SIGNIFICANCE OF NEUTROPHIL TO LYMPHOCYTE RATIO, PLATELET TO LYMPHOCYTE RATIO AND LYMPHOCYTE TO MONOCYTE RATIO IN PERIPHERAL BLOOD OF PATIENTS WITH BENIGN AND MALIGNANT ORAL LESIONS (Abstract): Local inflammation appears to play a very important role in the apparition and development of local tumors and metastases. The aim of this study was to determine the importance of neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR) and lymphocyte-to-monocyte ratio (LMR) in patients with benign and malign tumors in the oral maxillofacial (OMF) region. **Material and methods:** Medical records of 387 patients diagnosed with oral maxillofacial malignant or benign tumor between January 2017 and June 2019 were retrospectively analyzed. Pretreatment neutrophil, lymphocyte, platelet and monocyte counts and their ratio neutrophil-to-lymphocyte ratio (NLR), lymphocyte-to-monocyte ratio (LMR) and platelet-to-lymphocyte ratio (PLR) were investigated. **Results**: From preoperative complete blood count (CBC) of 387 patients, 151 female and 236 male, 141 benign and 246 malign we found that NLR, PLR and LMR in patients with benign oral lesions were 2.26 (2.03-2.48; SD: 1.35). 107.97 (100.4473-115.5079; SD: 45.2274) and 4.88 (4.5423 to 5.2244; SD: 2.0484) while patients with malign oral lesions had 3.13 (2.85-3.41; SD: 2.95). 129.83 (122.0907-137.5865; SD: 61.6954) and 3.9 (3.6258 to 4.2452; SD: 2.4663). **Conclusions:** Determining NLR, PLR and LMR can be done with a simple investigation and can help determine the prognosis of patients with oral cavity cancer. Mean NLR and PLR in malign tumors was found to be higher than in benign lesions, while LMR was found to be lower in malign tumors than in benign ones. Furthermore, when combining them there is a greater chance of distinguishing a benign tumor from a malignant one. **Keywords**: LYMPHOCYTE-TO-MONOCYTE RATIO, NEUTROPHIL-TO-LYMPHOCYTE RATIO, AND PLATELET-TO-LYMPHOCYTE RATIO, ORAL CAVITY CANCER, BENIGN MALIGN LESION.

Oral cancer is one of the most common cancers worldwide. In 2002, 274,000 cases of oral cavity cancer were reported, of which nearly two thirds in men, thus occupying the 12th place in the world (1). In 2008 oral cancer ranks 15th in the world with 263,000 cases and 127,000 deaths (2) while in 2012 approximatively 300,000 new cases of oral cancer were reported, meaning 2.1% of the world total, with two-

thirds occurring in men and only one-third in women with almost 145,000 deaths (1.8% of the world total), of which 77% were in the less developed regions. The most common pathological type being squamous cell carcinoma (SCC) (3).

Local inflammation appears to play a very important role in the apparition and development of local tumors and metastases. Inflammation has a key role in cancer physiology by promoting carcinogenesis, primary tumor growth, stimulating the proliferation of tumor cells, inhibiting cellular apoptosis and increasing mitotic rates (4).

Inflammation is a complex biological response to cellular damage in which the immune system tries to eliminate or neutralize the infection and start the healing and regenerative processes.

It is possible that the tumor promoting inflammation, whether it precedes or follows the tumor apparition, is a normal process in response to local injury and infection that it is used by cancer cells to develop itself (5).

One such example of a connection between acute inflammation and cancer is shown in a recent study which emphasizes a higher risk of pancreatic cancer in patients who had acute pancreatitis (6).

Chronic infections are known to contribute to cancer initiation and progression by promoting angiogenesis. Also, chronic infections are considered etiological factors for many human cancers, Hepatitis B, Hepatitis C, hepatomas, *H. pylori* and gastric cancer, oral and cervical cancers (7).

Rapid differentiation of a benign oral lesion from a malignant one can be a real challenge in some cases. A correct clinical examination of the patient by inspection and palpation of the lesion is essential for a diagnosis. In addition to histopathological examination of certainty, there are also new non-invasive methods of detecting tumor cells in the oral cavity such as fluorescence imaging and salivary protoporphyrin examination (8).

NLR is a known marker for systemic inflammation that is easily obtained and measured with a simple blood tests and it has been shown to be effective in predicting the prognosis of cancer treatments.

Mean NLR values in healthy adult people was shown to be 1.65 (±1.96 SD: 0.78-3.53) (95%CI (0.75-0.81) in a study on 413 patients (9) while a study made on 12,160 patients without any cancer or other medical history showed a mean NLR across all ages of 1.65, with a mean NLR of 1.63 (0.76) for men and a slightly higher mean NLR for women of 1.66 (0.82) (10).

An elevated NLR indicates an aggressive or advanced tumor and an inflammatory microenvironment that enables a tumor to spread. A high NLR can mean a low lymphocyte who have tumor suppressing effects and/or a high neutrophil count which can cause angiogenesis enabling the tumor to spread (11).

Neutrophils are the most abundant cells found in early stage of acute inflammation while lymphocytes are mostly involved in chronic infections. Neutrophils and lymphocytes have reverse effects in cancer development. Neutrophils increase angiogenesis through vascular endothelial growth factor while T-lymphocytes can inhibit the spread of tumor cells.

Therefore, an elevated NLR, caused by neutrophilia and lymphopenia, is commonly observed in malign tumors (12).

The exact mechanism that can explain the association of high monocytes and a poor cancer prognosis is still unclear. Monocytes create proinflammatory cyto-

kines like IL-1, IL-6, IL-10 and TNF that are associated with poor prognosis and shorter overall survival in cancer. Furthermore, when stimulated they can produce monocyte chemo-attractant protein-1 that can mediate migration and infiltration of tumor associated macrophage which could promote angiogenesis and distant metastases in malign tumors (13).

MATERIAL AND METHODS

Information was collected from patients with histopathological confirmed oral and maxillofacial benign or malignant tumors admitted to the Oral Maxillofacial Clinic of the Craiova County Clinical Emergency Hospital between January 2017 and June 2019 resulting a number of 550 cases. Patients having any acute or chronic systemic inflammatory condition or no recorded neutrophil, lymphocyte, platelets and monocyte counts (n=163) were excluded resulting in a total of 387 patients available for analyses.

A positive diagnosis of oral maxillofacial benign or malign lesion has been established based on histopathological examination of an incisional biopsy, by taking part of an abnormal area of cells, or an excisional biopsy by removing all the area with abnormal cells within oncological safety margins.

All study subjects were divided into two groups based on histopathologic results. All malignant cases were placed in group 1 while the remaining nonmalignant cases, benign or premalignant tumors were included in group 2.

The data collected included: year of admission, sex, age, histopathological results, type of tumor (benign or malign), monocytes, neutrophils, platelets, leukocytes, AST, ALT, hemoglobin, creatinine, urea, glucose, secondary diagnosis, complications, surgery type and post-hospitalization evolution.

The neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR) and lymphocyte-to-monocyte ratio (LMR) were calculated and statistical analysis was performed using *MedCalc* 18.11.3 and *Microsoft Excel* 2016 v 1809. Using independent samples t-test and Receiver Operating Characteristic (ROC) we considered a value of $p < 0.05$ statistically significant.

The statistical analysis will be discussed from the perspective of: NLR, PLR, LMR, sex and age ratio, male and female, benign and malign.

RESULTS

There were totally 387 patients with an oral cavity lesion available with preoperative complete blood count (CBC) record and histopathological confirmation. Of these 387 subjects. 246 (63.56%) of them were diagnosed with malignant tumor and only 141 (36.43%) with nonmalignant lesion. 151 females (39%) and 236 males (61%) with an average age of 62.8675 ± 2.74 years and 61.8008 ± 1.62 years respectively. The malignant group was found to be older (65.5 ± 1.48 years) compared with the benign group (56.47 ± 2.82 years) (tab. I).

NLR mean for patients with benign oral lesions was 2.26 (2.03-2.48) with a SD 1.35. while patients with malign oral lesions had an NLR mean of 3.13 (2.85-3.41) and SD 2.25. This means a difference of 0.8725 NLR mean between benign and malign lesions, moreover, emphasized by the p result of 0.001 showing a clear difference in the inflammatory response between malign and benign lesions, with a higher inflammatory response in malign batch (tab. II, fig. 1).

TABLE I
Mean age

Age	Benign	Malign
Sample size	141	246
Arithmetic mean	56.4752	65.5081
95% CI for the mean	53.6478 to 59.3025	64.0265 to 66.9897
Variance	288.3655	139.1897
Standard deviation	16.9813	11.7979
Standard error of the mean	1.4301	0.7522
F-test for equal variances	P < 0.001	

TABLE II
NLR benign *vs.* malign

LR	Benign	Malign
Sample size	141	246
Arithmetic mean	2.2614	3.1339
95% CI for the mean	2.0359 to 2.4868	2.8507 to 3.4171
Variance	1.8337	5.0849
Standard deviation	1.3541	2.2550
Standard error of the mean	0.1140	0.1438
F-test for equal variances	p < 0.001	

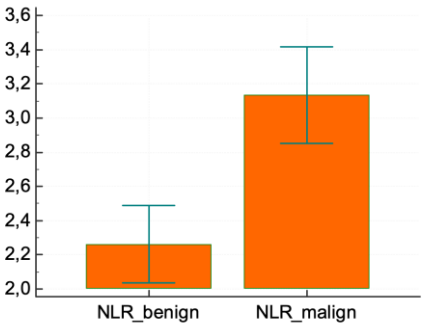

Fig. 1. NLR benign *vs.* NLR malign

Out of the 387 patients with oral lesions 141 were benign, 72 female and 69 males. NLR mean female was 2.26 (1.88-2.63) while NLR mean male was 2.25 (2-2.51). Thus, there is no significant difference between the male and female inflammatory response to benign lesions (tab. III).

From 387 patients with oral lesions, 246 were malign, 79 (32.1%) female and 167 (67.8%) males. NLR mean female was 2.62 (2.27-2.97) while NLR mean male was

3.37 (2.99-3.75). Also seen from the p value of 0.001 when assessing the inflammatory response in malign lesions there is a significant difference between men and female, with an increased response in male subjects (tab. IV).

The mean PLR in 141 oral benign lesions was 107.9 while PLR mean in 246 malign oral lesions was 129.8. The difference was caused because of lymphopenia in patients with malign lesions.

With a p value of 0.001 there is a significant difference in response between benign and malign groups (tab. V). Mean LMR was 4.88 (4.54-5.22) in patients with benign oral lesions and 3.9 (3.62-4.24) in malign oral lesions. With a p value of 0.016 there is a high association between the increased level of monocytes and the presence of malign or benign lesions (tab. VI).

DISCUSSION

Many meta-analysis on patients with oral maxillofacial cancer have shown that a high value of the NLR ratio is an unfavorable prognosis (14, 15).

Several studies on patients with oral

tongue cancer showed that for a pretreatment mean NLR above 2.93-2.95 there is an exponentially increasing chance of having a large invasive tumor with perineural invasion and neck metastases even in clinically negative neck (16, 17). In our study on 387 patients with malign oral tumor a mean NLR of 3.68 (2.96-4.4) was found in 58 (15%) patients (47 men and 11 women) that had neck metastases while mean NLR in subjects with no metastases was only 2.96 (2.66-3.26).

A recent study made on patients with oral cancer showed that LMR can be associated with T and N classification and pathologic stage while NLR is associated with T classification and pathologic stage and PLR with N classification and pathologic stage (18).

In oral squamous cell carcinoma (OSCC) higher neutrophil count correlate with lower overall survival (OS) while higher lymphocytes positively correlate with OS (7) resulting an NLR that can predict the OS in oral cavity cancer. Elevated NLR associated with C-reactive protein is significantly associated with malignant tumor, metastases, overall survival and disease-free survival (19).

In a study on 202 patients with oral cancer it was shown that in oral cavity cancer, the peripheral total white blood cell count, neutrophil and monocyte counts as well as NLR increased with the advancement of clinical stage while lymphocyte count was decreasing. Further, patients with lymph node metastases had monocyte count increased (20).

There is a growing interest in researching the correlation between inflammation, infection and cancer as it has been shown in several studies the existence of a direct connection between NLR, PLR, LMR and cancer prognostic.

The mean NLR values in healthy adult people was shown to be 1.65 (±1.96 SD: 0.78-3.53) (9, 10) while in our analysis on 387 patients, 151 female and 236 male, 141 benign and 146 malign we found NLR mean for patients with benign oral lesions was 2.26 (2.03-2.48) with a SD 1.35. while patients with malign oral lesions had an NLR mean of 3.13 (2.85-3.41) and SD 2.25. The ROC analysis suggested cutoff value of 1.9609 for NLR in predicting malignancy (fig. 2).

Elevated platelet count and platelet-to-lymphocyte ratio (PLR) was shown to be associated with poor prognosis in a meta-analysis made by (21). Mean PLR in healthy adult people is 132.4 (10) while we found a 107.97 (100.4473 - 115.5079) mean PLR in benign lesions and 129.83 (122,0907-137.5865) PLR mean in malign oral lesions.

In our study on patients with oral lesions, mean LMR was 4.88 (4.5423 to 5.2244) in patients with benign oral lesions and 3.9 (3.6258 to 4.2452) in malign oral lesions while mean LMR in healthy people is 5.31 (10). The ROC analysis suggested cutoff value of 3.2 for LMR in predicting malignancy (fig. 4).

Even though there is a small difference in the age-related variance between the two groups the data analyzed is relevant.

In our study, of the 387 patients, only 83 (21.44%) had all three inflammatory markers, namely NLR, PLR and LMR, in the malignant area suggested by the ROC curve analysis. Of these, only 12 (14.45%) had benign tumors and 71 (85.54%) malignant ones.

We further found 67 cases (17.31%)

who had NLR and PLR suggesting malignant tumor while LMR indicating benign of which 47 (70.15%) were histopathological confirmed to be malignant lesions and 20 (29.85%) benignant (tab. VII).

CONCLUSIONS

Patients with oral maxillofacial benign lesions had higher count of neutrophils and lower lymphocytes, meaning a higher NLR than healthy people while patients with oral malignant lesions had a mean NLR even higher. These results were in consonance with other studies that suggest the diagnostic role of NLR in differentiating nonmalignant oral lesions from oral cancers.

Stratifying the analysis, we have found no significant association between gender and inflammatory response in the benign batch of samples as opposed to the malignant counterpart where the association was significant with a higher relevance in the count of NLR in men.

The PLR ratio was also significant between malign and non-malign groups, while when referring to the LMR ration we have discovered a high association between malign and benign with a heavier load in the benign group, confirming the literature.

Furthermore, when combining the NLR, PLR and LMR in patients lacking any acute or chronic systemic inflammatory condition and that are not under any anti-inflammatory treatment, there is a greater chance of distinguishing a benign tumor from a malignant one.

There are also some limitations to our study which we have to emphasize, respectively the relatively small number of enrolled subjects which can be corrected in other studies by continuing the enrollment.

EPIDEMIOLOGICAL ASPECTS OF SYPHILIS (Abstract): Syphilis is the main venereal disease globally and one of the main problems of modern medicine, although its incidence is continuously declining. Aim: to gather data regarding the incidence of syphilis over the last 5-6 years in North-eastern Romania. **Material and methods**: Retrospective study on the main forms of syphilis (primary syphilis, secondary syphilis, latent syphilis, congenital syphilis, neurosyphilis) which included a total of 304 patients admitted and treated to the Clinic of Dermatovenerology of the Iasi County "Sf. Spiridon" Emergency Hospital between 2013-2018**. Results:** The incidence of the different clinical forms of syphilis was as follows: primary syphilis 1%, secondary syphilis 16%, recent latent syphilis 37%, late latent syphilis 22%, early congenital syphilis 3%, late congenital syphilis 11%, results on agreement with literature data. **Conclusions**: Our study demonstrates a linear decrease in the incidence of syphilis over the last 5-6 years in Northeastern Romania, but it still ranks first among EU countries. Further research is needed to understand the social determinants that lead to the spread of sexually transmitted diseases in Romania. **Keywords**: SYPHILIS, EPIDEMIOLOGY, SEXUALLY TRANSMITTED DISEASE.

Syphilis, a sexually transmitted infectious disease in most cases, has been the main venereal disease globally and is still one of the most important problems of modern medicine (1). In 1905, Schandinn and Hoffman (2) identified the causal agent of syphilis, *Treponema pallidum*.

Syphilis is an infectious disease with chronic, undulating course caused by the spirochete *Treponema pallidum*, which is transmitted through the skin and mucous membranes damaging all organs over time. Since the 16th century, syphilis is the most feared sexually transmitted disease (STD) worldwide (3-5). Syphilis is classified as acquired and congenital. Congenital syphilis is caused by the transplacental transmission of spirochetes and is associated with an increased rate of congenital malformations. In its turn, acquired syphilis is divided into early and late syphilis. The early form is classified as primary, secondary and early latent, and late syphilis includes late latent and tertiary syphilis (3,6).

Untreated syphilis can be fatal in over 60% of cases, mainly due to complications during the tertiary stage, and also facilitates the transmission of HIV infection. Most patients with syphilis are asymptomatic and do not realize that anything is wrong, the disease being detected following routine investigations (7, 8).

Annually, approximately six million new cases of syphilis are recorded globally in people aged 15 to 49 years. Over 300,000 fetal and neonatal deaths are attributed to syphilis. Syphilis rates in Eastern Europe increased dramatically after the collapse of the Soviet Union, contributing to changes in health infrastructure, sexual behavior and the emergence of the HIV/AIDS pandemic (8).

In Romania, during 1980-2009, the average annual incidence of syphilis was 25.2 cases per 100,000 population. The incidence had an upward trend during 1980-2002, subsequently declining dramatically during 2002-2009. From 2009 until now, the incidence of syphilis has been steadily declining, but is still one of the highest in the EU countries (9, 10).

Modes of direct transmission of acquired syphilis are sexual contact (90% of cases), extragenital route (wet kiss, accidental inoculation through stings, bites, continuity solutions, rarely encountered in practice), transmission through infected blood, saliva, semen, urine; indirect transmission through contaminated objects is exceptional (11).

The epidemiology of syphilis is influenced by a social, economic and civilization "macro context", as well as by a "micro context" related to individual factors: behavior, level of education and culture (12).

Globally, WHO estimates that most cases of syphilis are recorded in Asia and Africa and that in Europe 30,000-40,000 new cases occur annually. Epidemiological data regarding the incidence of syphilis in Eastern Europe are rare and inconsistent. The incidence of this disease is underestimated because some countries do not report all cases or report them with significant delays. On the other hand, some patients do not see a doctor when lesions occur, or the diagnosis is overlooked due to the similarity to many other conditions (7,13-14).

In Romania, in the last 50 years, the highest morbidity was recorded in 1972 (27 cases per 100,000 population) and the lowest in 1982 (5 cases per 100,000 population) (1). In 2007, Romania reported the highest incidence of syphilis in the European Union (2).

MATERIAL AND METHODS

Our study was a retrospective and observational one that included a series of 304 patients admitted to the Dermatovenerology Clinic "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, with the diagnosis of syphilis during 2013-2018. For each study patient the following data were collected: sex, age, area of residence, and disease status. 61% were male and 39% female, male/female ratio 1.53.

Statistical analysis. The data were centralized in a *SPSS version 18.0* database and processed with the statistical functions to which they are expected, at the significance level of 95%.

RESULTS

Of the total number of admission to the Dermatovenerology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, during 2013-2018, 3.2% were syphilis cases.

As shown below, 59% of the study patients resided in urban areas. The annual distribution of the study cases revealed a linear decline in the number of new syphilis cases. This constant decrease has a positive population-level impact, considering the socioeconomic issues this disease implies (fig. 1).

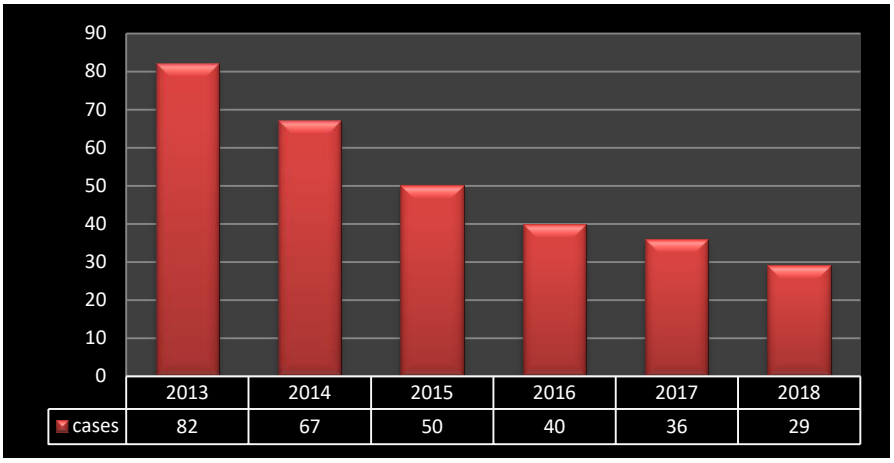

Fig. 1. Incidence of new syphilis cases during 2013-2018

Age group incidence rates were the highest in patients aged 20-49 years, which is the sexually active period (fig. 2). The youngest study patient was 15 years (female, with the diagnosis of secondary syphilis) and the oldest 82 years (male, with early latent syphilis). Mean age at the onset of syphilis was 41 years.

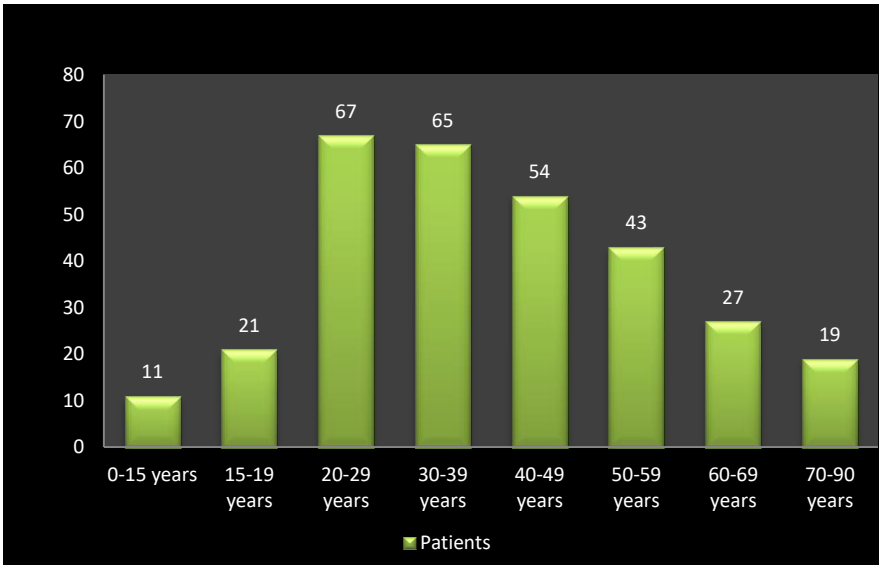

Fig. 2. Age-group distribution of the study patients

Of the 304 patients included in the study, 37% were diagnosed with early latent syphilis followed by 22% late latent syphilis, 16% secondary syphilis and 11% primary syphilis. A diagnosis of congenital syphilis was made in 40 patients, of which 11% had late congenital syphilis and 3% early congenital syphilis. In the interval 2013-2018, only one case of neurosyphilis was recorded (fig. 3).

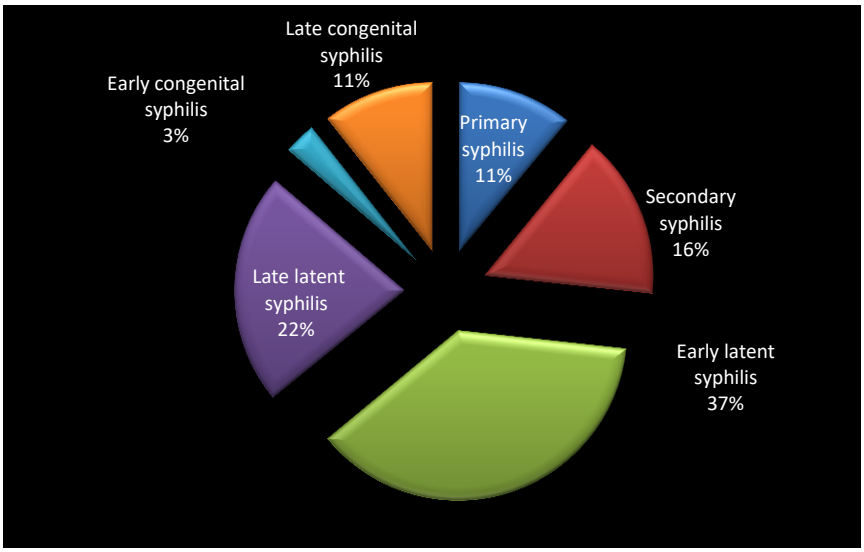

Fig. 3. Early latent syphilis, late latent syphilis, early congenital syphilis, late congenital syphilis, neurosyphilis, primary syphilis, secondary syphilis

DISCUSSION

Bjekic *et al*. (15) demonstrated in a 2014 study analyzing the epidemiological situation of syphilis in the population of Belgrade that the incidence of syphilis was higher in men. Also, in our study, the ratio of men to women was 1.53 and a possible explanation would be the first intercourse that occurs earlier in men that in women (16).

Most of the study patients resided in urban area, this agreeing with the data in the literature. In a study conducted at the Colentina Hospital in Bucharest, Sălăvăstru *et al*. (7) showed that the prevalence of syphilis is higher in the urban compared with rural population. The higher prevalence of syphilis cases in urban areas may be due to both better medical supervision and easier access of the population to medical services, which result in higher rates of diagnosis and appropriate case reporting. Similarly, urban residence has been associated with a high syphilis rates in studies conducted in America and Estonia.

Similar to our study in which young adults (20-39 years) were predominantly affected, Neghina *et al*. (9) showed a higher incidence of syphilis in the same age category in Romania between 1980-2009, Chesson *et al*. (17) found the highest incidence in persons aged 25 years in the United States (2007) and Rodriquez de Mingo *et al*. (18) showed that most cases (46.3%) registered at a health center in Madrid, Spain were under 35 years. Socioeconomic

and educational factors, pimping, as well as sexual assault of juveniles led to increased syphilis morbidity at ever younger ages (5).

These paper demonstrated that the incidence of syphilis in the Northeastern Romania is constantly decreasing (2013 - 82 cases, 2014 - 67 cases, 2015 - 50 cases, 2016 - 40 cases, 2017 - 36 cases, 2018 - 29 cases). Similar to these results, many studies in the literature indicate a decrease in syphilis cases. This reduction in the annual incidence of syphilis demonstrates improved screening and treatment programs in recent years, as well as a higher level of population health education. However, the incidence data obtained in Romania in recent years are significantly higher compared to those reported in other Western European countries (9).

Regarding the disease stage at the time of diagnosis, the majority of patients were in the early latent or late latent syphilis stages, which highlights that the disease was detected following routine serological tests. These data are in accordance to those obtained by Salăvăstru *et al.* in the study carried out at the "Colentina" Hospital in Bucharest between 2002 and 2006 (7). There are no visible symptoms at this stage, but serological evidence of ongoing disease can be found. Screening, and particularly of some population groups, such as pregnant women or medical students, is very important for detecting asymptomatic cases (19). Particular attention should be paid to congenital syphilis rate, as it may be underestimated. The diagnosis of congenital syphilis is challenging, more than half of all children being asymptomatic, and the signs in symptomatic infants can be subtle and nonspecific (9). In the last 70 years, with the decrease in syphilis rate due to the introduction of penicillin treatment, neurosyphilis rate has also decreased. This accounts for the fact that in the interval 2013-2018 only one case of neurosyphilis was reported in our clinic. Often when a patient presents with such neuropsychiatric manifestations as psychosis, mania, cognitive disorders, behavior changes, the diagnosis of syphilis is not the first suspected. Often, the patients with such symptoms were initially treated with psychiatric medication, although the appropriate treatment was penicillin. Thus, performing serologic tests for Treponema pallidum in patients with psychiatric manifestations is justified (19).

CONCLUSIONS

Syphilis is the third most common sexually transmitted disease in Europe. Raising awareness of the need for testing, knowledge of the main symptoms and signs of this disease along with improving the case reporting systems should be the most appropriate future measures to control the spread of disease. In 2016, the World Health Organization (WHO) launched a new strategy on sexually transmitted infections for 2016- 2021. The priority of this strategy is the elimination of congenital syphilis by implementing complex screening methods for pregnant women as well as for some target populations in order to reduce the number of cases by 90% .

It has been suggested that generally the spread of sexually transmitted diseases is related to international travel and migration. In Romania, this hypothesis is supported by high incidence rates in large cities, such as Bucharest and Constanța, the largest Black Sea port.

Our study demonstrates a linear decrease in the incidence of syphilis over the last 5-6 years in Northeastern Romania, but it still

ranks first among EU countries. Further research is needed to understand the social determinants that lead to the spread of sexually transmitted diseases in Romania.

ADVANCED CERVICAL CANCER SURGICAL TREATMENT CONSIDERATIONS (Abstract) : The aim of this study was to highlight the importance of surgical treatment in advanced cervical cancer (IIB-IIIB). **Material and method**: Data from 179 patients with cervical cancer, admitted in the Clinic of Emergency Surgery, "Sf. Ioan" Hospital, Iaşi, between January, 1st, 2003 and December, 31st, 2009, were collected. **Results**: A number of 11 cases (6.1%) cases were without any clinical response, so that they benefit by radical radiotherapy ; a radical surgical intervention was performed in the other 168 cases (93.7%), in 4-6 weeks after chemotherapy. No intraoperative complications were evidenced, but after surgical intervention we recorded : urinary troubles - 10 (6.5%) ; lymphedema – 3 (1.9%) ; posttoperative intestinal occlusions - 2 (1.3%) ; extended dynamic ileus - 2 (1.3%) ; phlebitis – 2 (1.3%) cases. **Key words**: CERVICAL CANCER, SURGERY, SURVEILLANCE

DUMITRU BAGDASAR - MEDICAL MALPRACTICE?

DUMITRU BAGDASAR- MEDICAL MALPRACTICE? (Abstract): The Law 95/2006 defines malpractice as "the professional error committed in exercising the medical or medical-pharmaceutical act, generating prejudices on the patient, involving civil liability of the medical personnel and the supplier of medical, sanitary and pharmaceutical products and services". Although the law mentioned above does not have a known history, through 1930s, acts of medical malpractice have existed since the begging of the first doctors. The well-known Romanian physician Dumitru Bagdasar, the founder of the Romanian Neurosurgery School, in 1935 was accused of having chosen to go on holiday in the province instead of checking on his patient who suffered from a brain tumor. While he was gone, the patient died following a puncture, but his survival chances would have been inexistent even if the renowned neurosurgeon had spent every minute by his bedside. Whereas generally the first reaction is to accuse the treating physician, this cannot always be the case. The physician's liability cannot be invoked in this case, given that there was no professional blame. Dumitru Bagdasar bequeathed to future generations a multitude of valuable information that can be put into practice even nowadays. Most of the time, given that is difficult to accept the idea that a loved one is no longer with us, the blame lies with the doctor who, although he makes every effort to help an individual, fails to save his life. **Keywords:** DUMITRU BAGDASAR, MALPRACTICE, PHYSICIAN'S LIABILITY.

"It is hard being a physician and mostly being a surgeon ! The nervousness surrounding the surgery itself; the anxiety of potential death, inherent for this profession; so many emotional states shattering your health and maybe altering the primitive feeling of human mercy". This is what the well-known Romanian physician Dumitru Bagdasar, the son of a peasant from the village of Roșiesti (1) – the founder of the Romanian Neurosurgery School – wrote in his dairy on the 9th of November 1935.

Nonetheless, his passion for neurosurgery never made him become overwhelmed with the emotions of the operating room. Indeed, his professional performance has been praised to this day (2).

Medicine and law are among the oldest human activities (3). The Law 95/2006 defines malpractice as *"the professional error committed in exercising the medical or medical-pharmaceutical act, generating prejudices on the patient, involving civil liability of the medical personnel and the supplier of medical, sanitary and pharma-*

ceutical products and services". Hence, medical errors may be committed regardless of a physician's specialty; the consequence is not only civil liability, but also criminal liability, which brings prejudice to both parties (3).

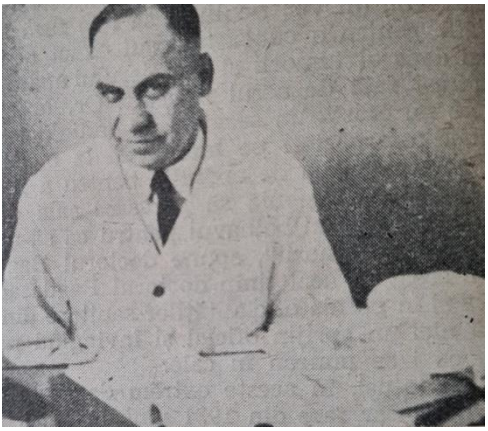

Fig. 1. Doctor Dumitru Bagdasar. (Photo source: Kreindler A, *Viața și opera profesorului Dr. Dumitru Bagdasar*) (2)

A physician's obligation is one of means; exceptionally, there are situations when they face the obligation of results. The prejudiced situation would prove the fact that they were the victim of a professional error. This solution may be found not only in our legislation, but also in Canada, Italy, Spain, or Belgium (4).

Many things have been written thus far concerning such cases; the authors were both legal and medical experts who – upon noticing certain things going wrong – have tried to issue a warning sign.

Across time, surgeons have developed a competitive spirit providing them with the opportunity to innovate, to change paths in many areas of medicine, but it has also brought them in an area of penumbra: I refer here to professional envy, accuses, or denunciations. The history of universal medicine and mostly the history of surgery abound in examples of the last category. The Romanian space is no exception. Important names of scalpel artists have been involved in malignant conflicts, such as the one between Thoma Ionescu and Victor Gomoiu. The Surgery Society – acknowledged from 1923 as a moral and legal entity – has included many meetings over time, where they discussed difficult patient cases, papers, surgical equipment presentations, and standpoints concerning the military situation and the war surgery. Dan Setlacec states – in a well-known writing – that "in our society, except for a few years with a low-key activity, the atmosphere was vibrant", "discussions were sometimes animated", and "scientific and non-scientific" controverses were expressed (5).

Deontological debates have also found a place among the discussions carried on by the members of the society, though they would make many of them feel rather embarrassed. Amza Jianu and Dimitrie Gerota brought up in 1928 a rather difficult topic for many years in the amphitheater: the abuse of surgical interventions, having nothing to do with a patient's affliction. Other sensitive topics included: self-granting scientific titles; details of course syllabuses; the selection criteria for physicians within various clinics; or the abuses and inconsistencies in the Criminal Code. The Surgery Society brought to the attention of its members the infamous Bagdasar-Vasiliu conflict (5).

On the 8th of September 1935, the journal named "Curentul" featured a piece titled *"For the redetermination of certain facts"* (6). Actually, one day prior, the same publication included an articled called *"The physician takes a walk"* (7). According to the authors, the latest article

had brought "a serious and unjust moral offence" against the famous physician Bagdasar; the authors wished to requalify the facts as they had occurred, for everybody to understand.

Therefore, the paper titled *"The physician takes a walk"* states that a physician's liability is a conscience-related matter, given that the patients put their trust in the physician. Persuaded that the specialists hold the knowledge necessary to heal them and that their moral values are noble, patients put their lives in the hands of a person with great surgical skills. However, the lines published in the journal *"Curentul"* describe the situation of a patient who died because of the negligence of a medical practitioner. Nicolae Popovici – the son of a well-known former school inspector – suffered from a brain tumor, reason for which he was admitted to the central hospital (7).

The well-known physician Dumitru Bagdasar was accused of having neglected to check on his patient, by *"remembering that summer was almost over and that he simply needed another relaxing escape to the province, to take advantage of the fine weather"* (6, 7) - the hospital ward remained under the supervision of an inexperienced young doctor. While he was gone, the patient died following a puncture, which stirred the anger of the person who wrote the article.

Therefore, in early 1934, N. Ionescu, MD and Ion T. Niculescu, MD – the authors of the article *"For the redetermination of certain facts"* – received the mission of consulting (along with other colleagues) Nicolae Popovici, admitted to the ophthalmology ward of the "Colțea" Hospital. The young man's condition worsened; symptoms indicated a brain tumor, and his life was in danger. However, the surgical intervention that saved him was performed by Dumitru Bagdasar; this intervention was recommended by all the neurosurgeons having consulted the individual.

In August 1935, Nicolae Popovici's health status declined. He was brought to Bucharest again, where he was admitted to the "French" Sanatorium. Along with the renowned physician D. Bagdasar, N. Ionescu, M.D. and Ion T. Niculescu, M.D. were summoned for a new consult. Given that the patient was not stable, the three decided to tell the family that it was impossible to carry out a surgery, because it was highly likely for the young man to die on the table; they recommended waiting for the patient to become stable and the family was informed expressly in this respect.

Meanwhile, the patient was transferred to the "Central" Hospital, in Bagdasar's ward. However, due to his very serious medical condition, Nicolae Popovici died but his survival chances would have been inexistent even if the renowned neurosurgeon had spent every minute by his bedside.

Whereas generally the first reaction is to accuse the treating physician, this cannot always be the case. The letter sent by N. Ionescu, M.D. and Ion T. Niculescu, M.D. had the role of clarifying that doctor Dumitru Bagdasar was not to blame; that he was passionate about his work and devoted to the service; all of his efforts –however great– had been in vain, unfortunately.

Most of the times, surgeons make superhuman efforts to save the lives of patients. It is extremely important to practice the profession diligently; to show compassion and patience in order to attain optimal results. The physician's liability cannot be invoked in the aforementioned case, given that there was no professional blame.

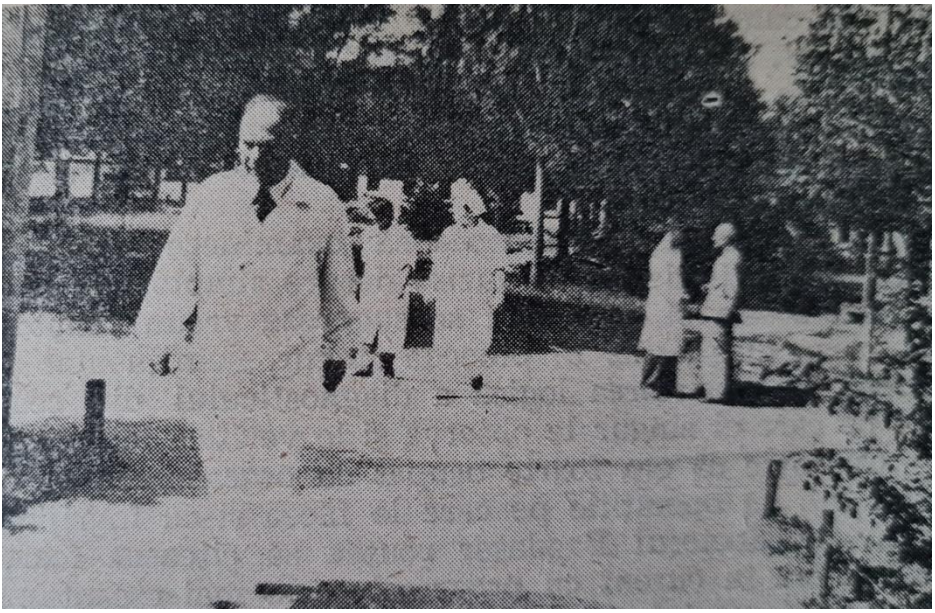

Fig. 2. Dr. Bagdasar at the Central Hospital.
(Photo source: Kreindler A, *Viața și opera profesorului Dr. Dumitru Bagdasar*) (2)

Dumitru Bagdasar represents a model for many neurosurgeons nowadays. His research in the fields of spinal cordotomies, of cerebral tuberculomas, and of spinal cord tumor pathology has been crucial for the current medical progress.

Despite all the struggles in his personal life, his medical passion was limitless: he helped those in need regardless of their social status.

TO WHAT EXTENT IS ROMANIA PREPARED TO JOIN HEALTH TECHNOLOGY ASSESSMENT COOPERATION AT EUROPEAN LEVEL

Silvia Gabriela Scîntee[1], M. Ciutan[1*], C. Vlădescu[1,2]

TO WHAT EXTENT IS ROMANIA PREPARED TO JOIN HEALTH TECHNOLOGY ASSESSMENT COOPERATION AT EUROPEAN LEVEL (Abstract): An increasing number of EU States are using the Health Technology Assessment (HTA) approach, and as health technologies, pharmaceuticals are one of the main fields of application in HTA. This is a review aiming to identify the current status of the HTA collaboration efforts in EU and in Romania, taking into consideration the growing role of HTA in decisions about the level of price and reimbursement in some EU countries or, in other countries, in decision on whether to reimburse a new product or to reject its funding totally. Romanian HTA system needs further development, both in terms of financial resources and, probably more important, human resources; the efforts in the long run will bring great returns to the entire health system, allowing better, safer, and more efficient use of pharmaceuticals and other health technologies. The scientific evidence provided may support the decision-making process. **Keywords**: HEALTH TECHNOLOGY ASSESSMENT, EVIDENCE BASED DECISION-MAKING HTA CORE MODEL.

The evidenced based decision-making process relays increasingly at EU level on assessing technologies that includes pharmaceuticals, devices, procedures, programmes, and even organizational aspects of health care systems. A widely accepted definition of Health Technology Assessment (HTA) was provided by European Network for Health Technology Assessment (EUnetHTA): "a multidisciplinary process that summarises information about the medical, social, economic and ethical issues related to the use of a health technology in a systematic, transparent, unbiased, and robust manner" (1).

HTA concept has been introduced in Europe stepwise since 1970s, and the formal collaboration among the national HTA agencies started in 1990s with financial support from the European Commission (EC) (2).

EUnetHTA Collaboration (3) was launched in November 2008, following an EC funded project aiming to connect national HTA agencies, research institutions and health ministries in order to enable an effective exchange of information on health technologies effectiveness thus assisting the EU Member States and candidate countries to plan, deliver and monitor health

services effectively (3). The first EUnetHTA Joint Action (2010-2012) built on the previous project results for developing an effective and sustainable HTA collaboration in Europe (3). EUnetHTA Joint Action 2 (2012-2015) improved the EUnetHTA tools and methodologies based on results of cross-border collaborative practical application of these (3). EUnetHTA Joint Action 3 (2016-2020) is strengthening the collaboration among EU Member States by an increased number of commonly evaluated technologies, revision of methodologies, development of quality standards and mechanisms to ensure uptake at national level, in order to establish a permanent HTA working structure for Europe (3).

Despite all attempts starting in early 1990s, Romania has set an HTA agency in 2012 only as a consequence of Directive 2011/24 EU. Initially established as a unit within the Ministry of Health, since 2014 it passed under the National Agency for Medicines and Medical Devices (NAMMD) (4). A 2017 World Bank financed project on Technical Assistance for institution building of HTA structure, including training for the NAMMD had the objective of making recommendations on further development of HTA system in Romania.

MATERIAL AND METHODS

The current study is a review of the main EU regulations, of national HTA legislation, of literature and working documents regarding the HTA Romanian system and EU cooperation in HTA. For the main consulted documents see first table.

TABLE I

Main consulted documents

- Directive 2011/24/EU of the European Parliament and of the Council of 9 March 2011 on the application of patients' rights in cross-border healthcare;
- Commission Implementing Decision of 26 June 2013 providing the rules for the establishment, management and transparent functioning of the Network of national authorities or bodies responsible for health technology assessment;
- Rules of Procedure of the Health Technology Assessment Network adopted by the HTA Network on 10 november2016;
- Proposal for a Regulation of The European Parliament and of The Council on Health Technology Assessment and amending Directive 2011/24/EU;
- Commission Staff Working Document on Impact Assessment Strengthening of the EU Cooperation on Health Technology Assessment (HTA) Accompanying the Proposal for a Regulation of the European Parliament and of the Council on Health Technology Assessment and amending Directive 2011/24/EU;
- Law 95/2006 on the Healthcare Reform;
- Ministry of Health Order 861/2014 for the approval of HTA criteria, documentation to be submitted by applicants, methodological instruments used in the assessment process concerning inclusion, extension of indications, non-inclusion or exclusion of medicines in/from the List of INNs of medicines from which the insured persons benefit, as well as INNs of medicines granted in national health programmes, and the means of challenge;
- Studies on mapping of HTA organizations and methodologies commissioned by European Commission;
- Technical assistance reports of the World Bank project conducted in Romania.

The list of the main consulted documents

A comparative analysis was performed following the developments of HTA at the European Union level and the development of HTA system in Romania.

RESULTS AND DISCUSSION

EU cooperation on HTA.

It is unanimously accepted all over EU that HTA has an important input on evidence-based decision-making.

The EC has supported the cooperation between HTA bodies, through substantial financing of three Joint Actions (JAs): 2010-2012 JA1 (6 million Euros), 2012-2015 JA2 (9.5 million Euros), 2016-2020 JA3 (20 million Euros) (fig. 1).

EU has facilitated the cooperation on HTA in Europe by creating the legal basis of an HTA Network. The article 15 of Directive 2011/24/EU on the application of patients' rights in cross-border healthcare introduces the setting up of a voluntary network to support cooperation between national authorities or bodies responsible for HTA (5). All EU countries have applied for membership and participate. Romania applied for membership and participated in all the Network's meetings through the MoH, mandated by the Law 95/2006, article 922 (6).

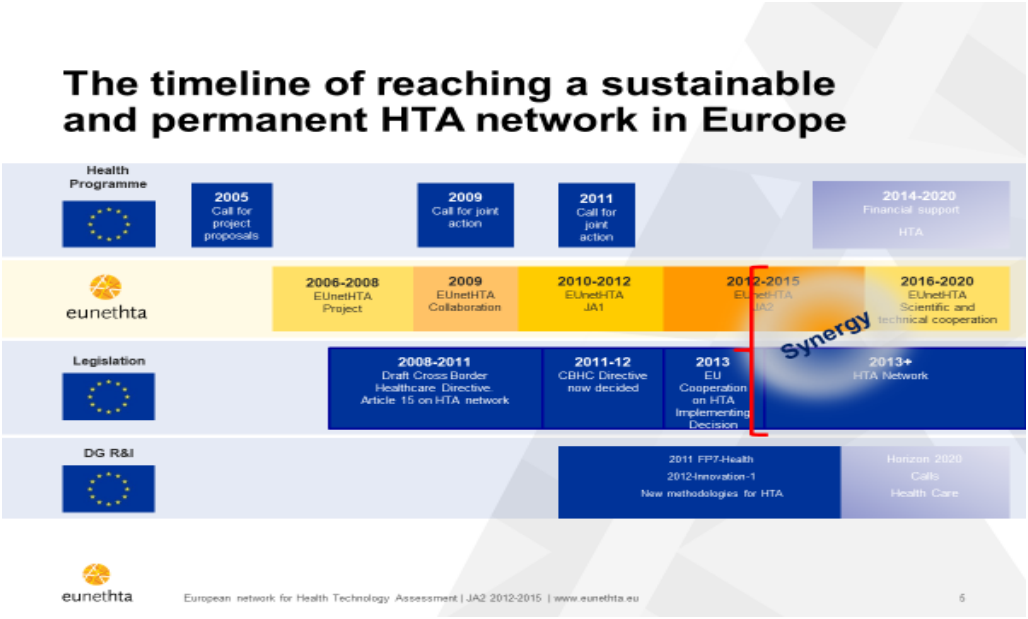

Fig. 1. The timeline of reaching a sustainable and permanent HTA network in Europe
Source: General Presentation on EUnetHTA
(https://www.eunethta.eu/general-presentation-on-eunethta)

The HTA Network's activity is regulated by the Commission Implementing Decision of 26 June 2013 providing rules for the establishment, management, and transparent functioning of the Network of national authorities or bodies responsible for HTA, that created a synergy between HTA Network and EUnetHTA Joint Actions (7),

stating "HTA Network shall be supported by a scientific and technical cooperation mechanism" (8). The HTA Network has also adopted owns Rules of procedures, a 2016-2020 Strategy for EU cooperation on HTA and developed Multiannual Working Programmes.

Thus, while the HTA Network is focusing on strategic issues and takes decisions relevant to EU cooperation on HTA, the currently EUnetHTA JA3 ensures scientific and technical cooperation for the HTA Network.

EUnetHTA collaboration. The scientific work in EUnetHTA Joint Actions, over the last 10 years, resulted in a specific set of tools and methodologies, handbooks and toolkits for users, teaching materials, internal strategies and methodological standards, guidelines and procedures manuals, databases, recommendations on the implementation of sustainable European network for HTA, position papers and reports. The final outcome of these JA consisted in the Joint or Collaborative Assessments of different health technologies produced by partners from different European countries.

The Network has been growing fast. If the first EUnetHTA JA counted 33 partners and 26 collaborators from 25 countries, the 3rd JA includes 81 organizations from 29 countries. The National School of Public Health, Management and Professional Development Bucharest joined EUnetHTA in 2011, and two more Romanian institutions in 2016: The National Institute of Public Health and the "Babes-Bolyai" University from Cluj-Napoca (3).

The main methodological framework for production and sharing of HTA information is *HTA Core Model* that collects information on nine domains: Health problem and current use of technology, Description of health technology, Safety, Clinical effectiveness, Cost and economic effectiveness, Ethical analysis, Organisational aspects, Social aspects, Legal aspects. The model reflects the broad scope and multidisciplinary nature of HTA (9).

Designed in EUnetHTA 2006-2008 project, the model has been refined along the 3 JAs, especially following its piloting, being currently at its 3rd version, and is still under revision. The HTA Core Model for the production of core HTAs (version 3.0) consists of three main components: (1) Standardised set of HTA questions (the ontology) that helps to define specific research questions; (2) Methodological guidance to assist in answering the research questions; (3) Common reporting structure. In its development, the Core model has been piloted on seven non-pharmaceutical technologies. The HTA Core Model is accessible free of charge but subject to the HTA Core Model Licence (10).

Given the complexity of the HTA Core Model, it was also developed an application for rapid assessments – *the HTA Core Model for Rapid Relative Effectiveness Assessments (REA)* that covers only four domains: Health problem and current use of technology, Description of health technology, Safety and Clinical effectiveness (fig. 2). REA was initially developed for pharmaceuticals in order to allow the assessment in the limited timeframe of 90-180 days imposed by the European Transparency Directive 89/105/EEC. Equally the Full Core Model, the Core Model for REA was continuously improved based on several pilots and its application was expanded to non-pharmaceutical technologies such as devices, diagnostics, surgical interventions, and screening (10).

The aim of EUnetHTA JA 3 is to define and implement a sustainable model for cooperation on HTA in Europe after 2020 by supporting the collaborative production of HTA and encourages the use of the HTA reports at national level (11).

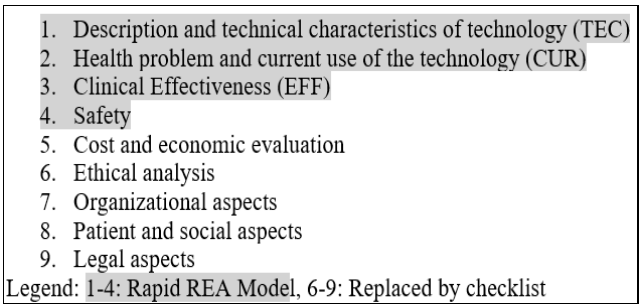

Fig. 2. The domains of the HTA Core Model and relative effectiveness assessment. Source: EUnetHTA WP5. HTA Core Model for rapid relative effectiveness, 2015

The updated list of assessments performed during EUnetHTA JA3 or planned to be performed is available on EUnetHTA website (12). The National School of Public Health, Management and Professional Development Bucharest (NSPHMPDB) has been involved as co-author in five REAs, and as dedicated reviewer in one REA, all for non-pharmaceutical technologies, adding on the experience acquired in JA2 from participation of the piloting of three Full Core HTA assessments. A list of technologies assessed during the EUnetHTA JA 3 with NSPHMPDB' contribution is present ed in second table.

TABLE II

List of technologies assessed during the EUnetHTA JA 3, with contribution of NSPHMPDB.

Pharmaceutical technologies assessed	Publication of Final Assessment
Hypoglossal nerve stimulation systems for treatment of obstructive sleep apnoea	21.05.2020
Biodegradable rectum spacers to reduce toxicity for prostate cancer	24.04.2020
Point-of-care Tests (POCT): D-Dimer and Troponin	14.08.2019
Screening for osteoporosis in the general population	19.12.2018
Bioresorbable Stents in cardiovascular indications (coronary artery disease)	20.08.2018
Antibacterial-coated sutures versus non-antibacterial-coated sutures for the prevention of abdominal, superficial, and deep, surgical site infection (SSI)	06.10.2016
Use of Intravenous immunoglobulins for Alzheimer's disease including Mild Cognitive Impairment.	30.11.2015
Structured telephone support (STS) for adult patients with chronic heart failure.	30.11.2015
Fecal Immunochemical Test (FIT) versus guaiac-based fecal occult blood test (FOBT for colorectal cancer screening.	31.07.2014

Source: Assessments REA (2016 – 2021) (https://eunethta.eu/rapid-reas/)

EU collaboration after EUnetHTA. During JA3, there were performed several evaluations to identify challenges and shortcomings of EU collaboration on HTA

after 2020, either by EUnetHTA, having in mind the aim of preparing for a sustainable network post 2020, or by the European Commission, in the view of preparing further regulations.

According to a study commissioned by EC in 2017, there is a large variety of organizational structures of national HTA models in EU and EEA countries, from large single HTA bodies, specially assigned working groups in the Ministry of Health, to systems with two or more organizations performing various functions in the national HTA processes or constituted in regional networks (13).

As well, an impact assessment performed in the view of issuing the Proposal for a Regulation of the European Parliament and of the Council on HTA and amending Directive 2011/24/EU, reveals that national HTA systems in Member States differ not only in the procedural frameworks and methodologies, but also there are significant differences in the available resources. Having identified all shortcomings, the study also presents an in-depth analysis of four policy options as further steps: (1) No Joint Actions after 2020; (2) Project-based cooperation on HTA activities; (3) Permanent cooperation on common tools, procedures, and early dialogues; (4) Permanent cooperation on common tools, procedures, early dialogues, and joint REA (14).

Based on the previously mentioned study, the EC adopted in 2018 a legislative proposal by which to reinforce cooperation amongst Member States, building on the policy option 4. Thus, the Member States will work together on joint clinical assessments of new medicines and certain new medical devices, on joint scientific consultations for developers, on identification of emerging health technologies and on voluntary cooperation in other areas. Individual EU countries are responsible for assessing non-clinical (e.g., economic, social, ethical) aspects of health technology and making decisions on pricing and reimbursement (15). The proposal is still under discussions, even if according to initial planning it should have been adopted by the Parliament and the Council in 2019. The last published progress report dates from June 2019, when the Council was under Romanian Presidency (16).

Stage of development of HTA system in Romania. The national competent authority for HTA in Romania is set as a unit within the National Agency for Medicines and Medical Devices, and the evaluation methodology is provided by the Ministry of Health Order no. 861/2014. The methodology is not relaying on assessment of evidence but is based on a scorecard system that relays mainly on decision-making in other countries (4,17,18).

As well, the HTA unit is not supported by adequate human resource capacities. A World Bank project was undertaken in Romania in order to provide recommendations for the further development of the national HTA system. In June 2017, the Technical Assistance Report presented three alternative models for the institutionalisation of HTA in Romania, taking into consideration the spread limited capacities in the country (19). At the time of writing no decision was taken in this regard.

Until developing the capacity of doing own assessments, Romania cannot actively participate to the joint clinical assessments as envisaged by the European Commission for the further EU collaboration on HTA. For being able to participate to this process, further steps should be taken in developing

the legislation, training human resources, and ensuring collaboration between existing experts in the field at national level.

CONCLUSIONS

The EU collaboration on HTA still faces a lot of challenges and barriers, from language use and reporting structure to differences in national processes and methodologies and the use of HTA report in decision-making. The EUnetHTA collaboration is aiming to develop an effective and sustainable HTA collaboration, through 1) reducing repetitions and improve the efficiency in the use of resources; 2) facilitate growing impact of HTA in EU Member States; 3) consolidation the relation between HTA and health care decision-making; and 4) supporting countries with less experience in HTAs. The benefits for HTA agencies that contribute to and use EUnetHTA assessments are resource- and time-savings. But, to achieve this, the national agencies should align to EUnetHTA practices in terms of topic selection, scope, and quality of the assessment (11). These initiatives intend to harmonize or standardize the HTA processes so to improve their level of transparency, quality and comprehensiveness, and facilitate the extraction of relevant information that can then be transferred cross-border.

In many countries, even high-income countries, the staffing levels of public authorities tasked with HTA, pharmaceutical pricing, procurement and reimbursement are low, and this is also true for the Romanian health system (20).

As well, EU collaboration on HTA require not only HTA agencies commitment, but also clear involvement and engagement from all stakeholders: industry, patients, healthcare providers and payers (18,19,21). From this perspective it can be argued the role of HTA in Romania is still undervalued, even if calls for increased efficiency and better methods for reimbursement and pricing for drugs are ten years old (20,22). In order to be able to use HTA and to participate to EU collaboration, Romanian HTA system needs further development, both in terms of financial resources and, probably more important, human resources; the efforts in the long run will bring great returns to the entire health system, allowing better, safer, and more efficient use of pharmaceuticals and other health technologies.

CONFLICT OF INTEREST

The authors reveal no conflict of interest concerning the manuscript.

BRÂNCUȘI-GEROTA "ÉCORCHÉ" 120TH ANNIVERSARY SINCE ITS COMPLETION (Abstract): The Écorché or "Ecorșeul", is the first of the many works of art done by Constantin Brâncuși, the world-renowned Romanian artist. It was achieved in collaboration with the famous anatomist Prof. Dr. Dimitrie Gerota and represents a national premiere in being the first anatomical work conceived in such detail in 20th century Romania. The debutant artist assimilated knowledge about the human anatomy from the dissection of human bodies, this being a process which harmoniously binds art with the study of anatomy. Inspired by Antinous's statue, Brâncuși used, in his work, its stature and flamboyant pose. Awe-inspiring are the copies of Brâncusi's Écorché, which, worked in plaster and attentively supervised by Brâncuși. They were donated later to Medical Schools and Art Schools around Romania for academic study. The Écorché, which was realized with intense efforts, brings national and international renown to the young sculptor, at the very start of his carrier, which became, with the passing of time, a work linked closely to his name, despite the modernist and abstract current which embodied his whole carrier. **Keywords:** CONSTANTIN BRÂNCUȘI, DIMITRIE GEROTA, ÉCORCHÉ, HUMAN ANATOMY, HISTORY OF MEDICINE.

EARLY LIFE

Constantin Brâncuși, the absolute artist of Romania, a faithful militant of the infinity he created with his own hands, is considered the parent of modern international sculpture.

The genius with magic hands, has learned his trade at the beginning of the 20th century, when he finished his studies at the National Arts School in just four years, where he cultivated his perseverance and workmanship.

The pinnacle of his career, however, was to be found in Paris, where after great sacrifices, he managed to be admitted to the *"Ecole Nationale Superior des Beaux Arts".*

It is here, in Paris, where he spent a large part of his later years, after having completed some of his greatest works and after having received a substantial number of distinctions awarded by multiple French art association.

THE ÉCORCHÉ, MORE THAN A WORK OF ART

The "Écorché", or "Ecorșeul", in Romanian, represented the first large-scale

work of young Brâncuși and it is an art piece which proves his artistic genius to this day. It was realized during his studies in Bucharest and represents one of Brâncuși's most different and impressing work of art.

The Romanian word "Ecorșeu" comes from French and has the same root word as in English, namely "Écorché". It means a representation by drawing, painting, or sculpture of the human body devoid of skin and its three layers.

As stated in the abstract, the work was done under the careful guidance of Prof. Dr. Dimitrie Gerota, who helped young Brâncuși acquire the foundations of anatomical knowledge, so essential for the correct realization of the "Écorché".

In this regard, Prof. Dr. Dimitrie Gerota, procured the dissection materials "according to nature, directly human, the bodies being recovered from the Bucharest Faculty of Medicine, from professional works and from the city's mortuary" relates the "Brâncușian exegesis expert" V. G. Paleolog.

The work of dissection was carried out by both Brâncuși and Prof. D. Gerota, the goal of which was the establishment of the perfect proportions for the anatomical casts, which were later used to create the baseline through which the "Écorché" was made.

Brâncuși received his ideas from "The Artistic Anatomy" of Paul Richet and from the dissection courses which he follows at the Bucharest Faculty of Medicine, with the goal of bettering his knowledge (1).

The genius sculptor does all these works in a spirit of sacrifice, "for art's sake", which after morbid experiences, he begins to detest "the carnal", and even calls the human flesh "biftec" (Romanian word for beefsteak) (1).

The repulsion, which the artist develops, will be reflected in his future sculptures in which human traits are replaced by perfection, shaping the human ideal according to his aesthetic eye.

The "Skinned" (as Brâncuși nicknames the Écorché) was a subject that, indeed, treated the human body from both the perspective of art and the perspective of anatomy. This conviction is reinforced by the very model that Brâncuși will be inspired by, namely a copy of the sculpture 'Hermes Capitoline', located at the Capitoline Museum in Rome. This replica is present at the School of Fine Arts in Bucharest (fig. 1), and it was known as "Antinous" at the time. It was made available to the young sculptor who, will use the stature and pose of the statue, to achieve the "Écorché" (2).

From the artist's account to V. G. Paleolog, we learn that the muscles on some bodies were dissected individually and compared directly to the statue of Antinous. Therefore, we can say that the "Écorché" is an "ecorched" "Hermes Capitoline", or as Brâncuși would say, skinned (2).

In the summer of 1901, with the anatomical study soon to be completed, Brâncuși is rewarded at the Anatomy Competition (judged by Prof. Gerota) with the Bronze Medal.

The distinction seeming to have, indeed, been a thorough encouragement for the young artist. There were also some scholarships that he subsequently obtained for the carrying out and completing of the work.

It bears reminding that with the completion of the Écorché, he receives national notoriety, from which point on he is rewarded a number of distinctions at Artistic Youth exhibitions in Romania (3). This is

the moment when he becomes consecrated, in the minds of, if not the international public, yet, certainly the national one, as a master sculptor in his own rights.

The completion of the work takes place sometime in 1902, the exact date being unknown until nowadays.

The first exhibit of the Écorché, towards the greater public happens at the Romanian Athenaeum, in Bucharest, in 1903, it enjoyed nation-wide recognition ever after.

We shall now mention the friendship that Prof. Gerota and Constantin Brâncuși have had, because of their collaboration (4).

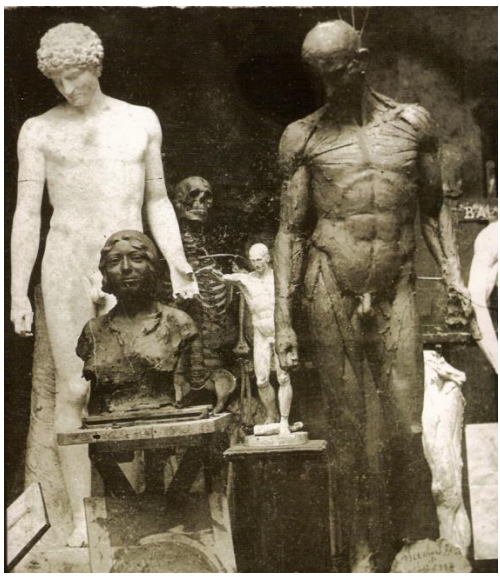

Fig. 1. Original photo held by Brâncuși, depicting the écorché, in progress, next to the statue of Antinous (taken from: Dumitrescu E, "Ecorșeul Brâncuși-Gerota istoria unei lucrări realizate la Școala de Belle Arte din București") (1)

Despite the age difference of nine years, the two continued their relationship after the artist left for Paris, with the remaining correspondence proving this. The connection between them may well be due to their common origin, the two being from the same region of Romania, Oltenia.

DIMITRIE GEROTA'S CONTRIBUTION

Prof. Dimitrie Gerota (fig. 2) was considered the first radiologist in Romania, offering a huge contribution to the foundation of this discipline in our country. At the same time, he was a passionate anatomist, being the founder of a museum of anatomical-surgical casts for students. Prof. Gerota, a true teacher, supported Brâncuși's work with the desire to offer a model of anatomical study at the level of the entire Romanian Universitary Community.

And that he did, ordering faithful copies of the Écorché, recreated in plaster, which were donated/sold to medical schools all over the country.

One of the most well-known and well-preserved specimens is still in Iassy, where it was sent by Prof. Gerota through the Ministry of Cultural Affairs in June 1903.

This colorful mold was used both at the Faculty of Medicine in Iassy and, at the School of Fine Arts for the studies of plastic anatomy.

The renowned anatomist from Iassy, Dr. Ștefan Possa had bought the Écorché for the sum of 10,000 lei, a considerable amount at that time (4).

Since two World Wars followed the purchase, it was assumed that the location of the Iassy "Écorché'' has been changed many times, without appearing on the inventory recorded by the educational institutions.

It appeared in several archives from the interwar period, and then only in 1966 is it recalled in a letter accompanied by a photograph.

Fig. 2. Professor Doctor Dimitrie Gerota (taken from: Dumitrescu E, "Ecorșeul Brâncuși-Gerota istoria unei lucrări realizate la Școala de Belle Arte din București")

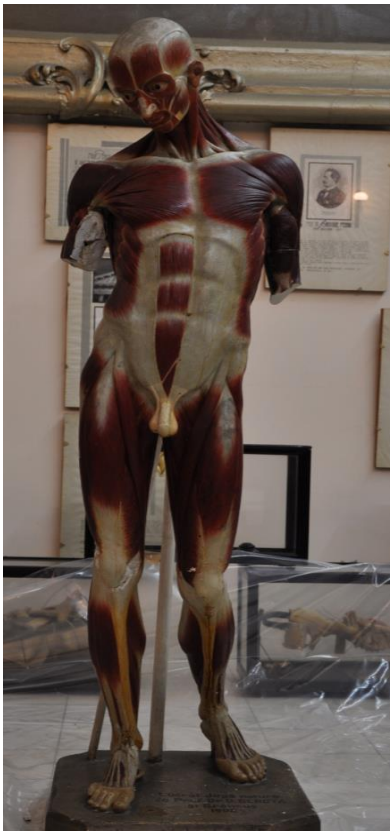

Fig. 3. The original from Iassy, during the restoration of the piece, sometime at the end of 2012 / original photography by Felix Aftene

Over time, small reconditioning took place on this specimen, but the most important was carried out in 2012 under the guidance of Felix Aftene. Both arms/hands of the mold were restored, these having been the most altered components. Today, the faithful copy of the Écorché (fig. 3) is located at the Anatomy Museum of the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi, along with other "ecorched" pieces and anatomical preparations, which constitute an impressive heritage of this prestigious institution.

Significant for the Iassy copy, is the mold socket, where the two authors were signed: "Prof. Dr. Gerota and Brâncuși" in 1902.

Today, there are known to be four authentic copies, which are located throughout Romania, in Iassy, Cluj-Napoca, Craiova and in Bucharest. The Original (fig. 4) can be seen till today, at the entrance of the National Art University in Bucharest, its dimensions being 177 x 52 x 32 cm (5).

As a mention, at the exhibition organized at the Brummer Gallery in New York, in the year 1933, Brâncuși especially wanted that on one of the walls to be placed a photo of the "Écorché'', a work that all biographers catalogued as a "schoolwork" (5). This was done to show the critics of his art style, that the evolution of his artworks had a natural course and that all the synthesis capacities he had attained through his masterpieces were derived from a deep and thorough knowledge of the human body.

CONCLUSIONS

We can firmly affirm that the joint work of Constantin Brâncuși and Professor Doctor Dimitrie Gerota revolutionized the study of myology in Romania, taking on a vital importance for Anatomy schools and

Fine Arts schools throughout the country. We cannot imagine the learning difficulties that the Romanian students of the 20th century would have gone through in the absence of materials such as the "Écorché" and its special copies. Today, young people have at hand the technology that, through various 3D applications, presents the anatomy of the human body at the click of a button, but then, in the absence of teaching materials, it was almost impossible to provide an overview of the "skinned" body, of human myology, and as a result, Brâncuși's creation was like "a breath of fresh air" for the anatomical study in Romania at the time.

Undoubtedly, the "Écorché" has become an anatomical and artistic symbol that will endure over the centuries.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

THE IMPACT OF VIRTUAL REALITY IN EATING BEHAVIOR

Obesity prevalence has increased in the last decade all over the world. Environment is one of the many factors that have an impact on eating behaviors and the prevalence of obesity. In reality, eating behavior such as of portion size perception, energy density, and taste, has changed over the years, as a result of the decrease of home-cooked meals consumption. Virtual reality can be used as a tool to study the impact of environments on eating behaviors, offering sensory information, as well as environment change. In this study participants masticatory cycles, heart rate, as well as skin temperature were tested in various scenarios: a restaurant and an empty room with a table. In both scenarios participants consumed pizza, masticatory rhythm and heart rate modification, as well as skin temperature variation, occurring only amongst those exposed in the restaurant context. Thus, virtual reality can conduct to a better understanding of environments impact on eating behaviors (Oliver JH, Hollis JH. Virtual Reality as a Tool to Study the Influence of the Eating Environment on eating Behavior: A feasibility Study. *Foods* 2021; 10(1): 89 / doi: 10.3390/foods10010089.).

EARLY LYFE

Leonardo da Vinci (born April 15, 1452, in Florence, died May 2, 1519 in France) (fig. 1) was an Italian painter, engineer, encyclopedic personality and remarkable neuroanatomist. He was born from Leonardo di ser Piero da Vinci, a wealthy notary and landlord from Florence, and Caterina de Meo Lippi, a young peasant woman. Due to his wealth status, da Vinci couldn't afford a superior education, so he received an elementary education from his paternal grandfather Antonio, which consisted in reading, writing and learning arithmetic skills.

After his father took him to Florence, when he was 15 years old, he had the opportunity to develop his drawing interest from artist Andrea del Verrocchio (1435-1488), which introduced the young da Vinci in painting, sculpture, technical-mechanical arts, geometry, arithmetic, chemistry, metallurgy and woodworking. During his stay at Verrocchio's workshops, he met famous painters such as Botticelli (1445-1510), Ghirlandaio (1448-1494) and also worked in the workshop of artist Antonio del Pollaiuolo (1429-1498). Working simultaneously in two famous artists workshop was a defining experience for young Leonardo, and in 1472, at only 20 years old was accepted into the Painters' Guild of Florence, a secular organization that controlled the arts in Florence during Renaissance Era (1). He continued to work with Verrocchio for five more years before started his independent career, when his main point was to find a higher sense to human existence (2).

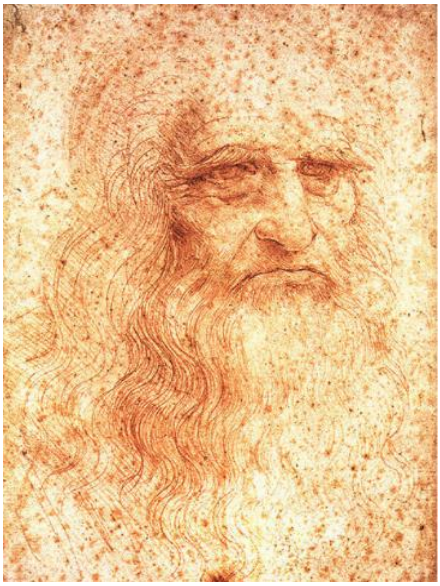

Fig. 1. "The portrait of a man in red chalk", self portrait of Leonardo da Vinci, ca. 1510 (public domain)

BEGINNINGS IN HUMAN ANATOMY

While working for Ludovico Sforza, Duke of Milan (1452-1508), his interest for understanding human anatomy and physiology began with anatomical drawings of animals. The practice of animal dissection was commonly used during da Vinci time for a better understanding of past scholars such as Hippocrates (460-370 BC) and Galen (129-216 AD) who studied usually on animals, to compare with human anatomy. Because human dissection was forbidden during Renaissance Era, da Vinci performed animal dissection until 1489. In a document dated from 1485-1487, da Vinci firstly described the pitching of a frog: "The frog retains life for some hours when deprived of its head and heart and all its bowels. And if you puncture the said nerve (spinal medulla), it immediately twitches and dies" concluding the fact that spinal cord was not only the source of semen, as beforementioned by Hippocrates and Plato, but actually the center of the body, naming it *virtu gienjitua* (generative power) (fig. 2) (3).

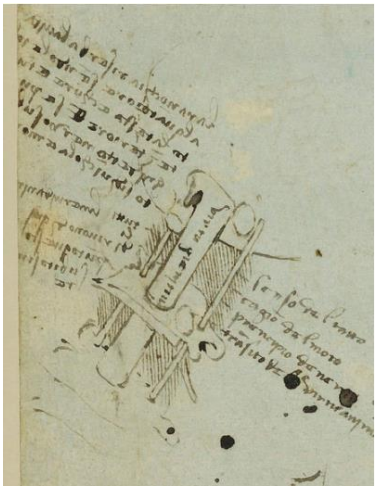

Fig. 2. Experiment with pithing the frog spinal cord, ca. 1485-1487 (public domain)

The study of anatomy was seen by da Vinci as a necessity for a better technique in his painting, his obsession with understanding nature processes and correlating anatomical parts with their function pushed him to perform human dissections, without any medical training, in the times when this practice was forbidden by the Catholic Church. Therefore, during 1489-1513 he actively learned through dissection on dead bodies and successfully described for the first time multiple anatomical structures (4).

REMARKABLE NEUROANATOMY AND NEUROSCIENCE DISCOVERIES

Da Vinci drawings were comprehensive, containing elements from both the Central Nervous System (CNS) and Peripheral Nervous System (PNS). In regard to CNS, he studied the morphological aspect of the skull and multiple intracranial structures (figs. 3, 4), to better the correlation between the eyes, brain and sight (5). Moreover, he performed dissections on nerve plexuses and peripheral nerves, precisely describing the main trunks of the brachial plexus and the ulnar, radial and median nerves (fig. 5), additionally. He explained in detail how sensitive and motor deficits are caused according to the specific area damaged, being a pioneer in the study of physiology (6). For lumbosacral plexus, he noted "There are as many nerves as muscles in the thigh" (7), and in a precise drawing of his, femoral, obturator and sciatic nerves can be observed (fig. 6). In the case of lower limb physiology, he noted the action of agonist and antagonist muscles before it was described by Sherrington (1857-1952).

Between the years 1506 and 1508 he mastered his knowledge of using molds for bronze sculptures, thus inventing a novel technique for studying neuroanatomy by injecting wax into the brains of oxen to create casts (8). This technique consisted in

injecting the molten wax inside the fourth ventricle and with this experiment, he was the first to accurately describe the lateral third and fourth ventricle, and also an interventricular foramen (fig. 7), who was described 200 years later by the Scottish physician Alexander Monro (1733-1817), named after himself as foramen of Monro. Leonardo da Vinci described the ventricular system being formed by three structures: *imprensiva* (anterior), *senso comune* (middle) and *memoria* (posterior). In plus, in his drawings, we can observe the foramen of Monro and aqueduct of Sylvius.

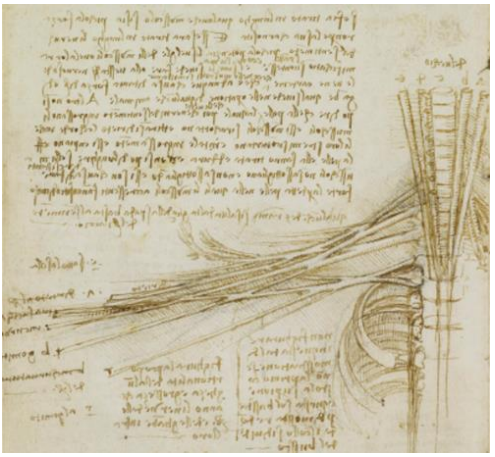

Fig. 5. Brachial plexus: superior, middle and inferior trunks are represented in detail, ca. 1508 (public domain)

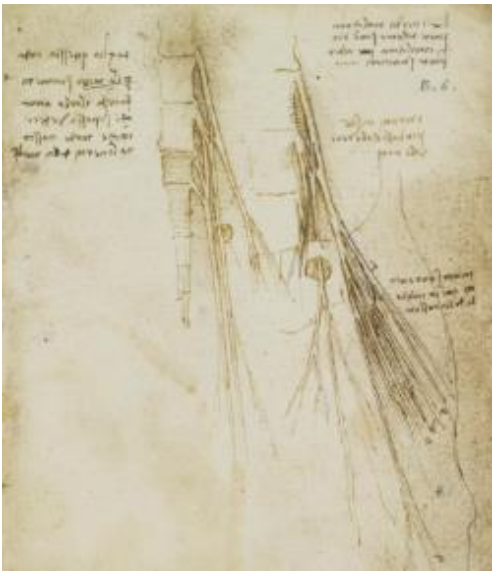

Fig. 6. Lumbosacral plexus: femoral nerve with his multiple branches, obturator nerve and a duplicated sciatic nerve (error), ca. 1508 (public domain)

Between the years 1506 and 1508 he mastered his knowledge of using molds for bronze sculptures, thus inventing a novel

technique for studying neuroanatomy by injecting wax into the brains of oxen to create casts (8). This technique consisted in injecting the molten wax inside the fourth ventricle and with this experiment, he was the first to accurately describe the lateral third and fourth ventricle, and also an interventricular foramen (fig. 7), who was described 200 years later by the Scottish physician Alexander Monro (1733-1817), named after himself as foramen of Monro. Leonardo da Vinci described the ventricular system being formed by three structures: *imprensiva* (anterior), *senso comune* (middle) and *memoria* (posterior). In plus, in his drawings, we can observe the foramen of Monro and aqueduct of Sylvius.

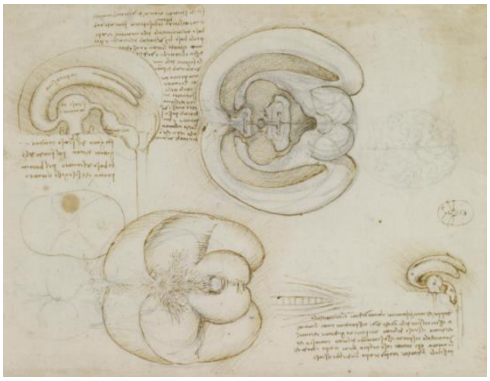

Fig. 7 – Ox brain injected with wax: ventricular system described as *imprensiva* (anterior), *senso comune* (middle) and *memoria* (posterior), ca. 1508 (public domain)

In a famous drawing of da Vinci, where he accurately describes anterior, middle and posterior fossae for the first time, and an impression of the anterior and middle meningeal arteries, the artist demonstrated the location of the *sensus comunis* (fig. 8), an intersection of three lines – an anterior-posterior axis, a lateral axis approximately along the ridge of the *dorsum sellae*, and a vertical axis through the upper point of the skull (9). All of those lines, intersect over the optic foramina, being on the anterior part of the third ventricle. He considered the soul as being located in the senso comune, maintaining the vision of others Galenic physicians (10).

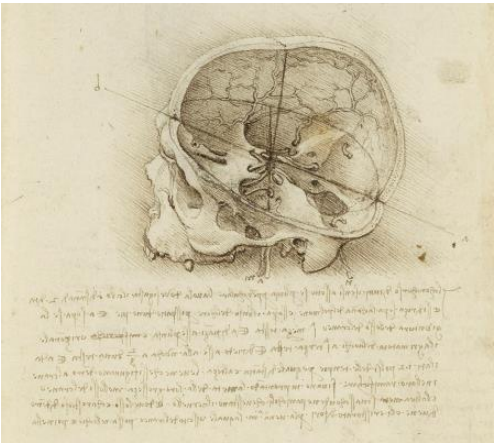

Fig. 8. Skull studies: senso comune represented by the optic chiasm, ca. 1489 (public domain)

One of the major objectives of Leonardo was to find a correlation between the nature and the soul, through the sense of sight (11). After many dissections on this matter, he concluded that we could see objects due to eyes receiving light. With this observation he contradicted classical thinkers like Plato, who considered the ability to see as a property of the eyes. Da Vinci noted “the eye, the window of the soul, is the chief means whereby the understanding can most fully and abundantly appreciate the infinite works of Nature” maintaining his point regarding a higher sense of the sight. Moreover, he was the first to describe the optic pathway and the first to consider the olfactory bulb as a cranial nerve (fig. 9) (12).

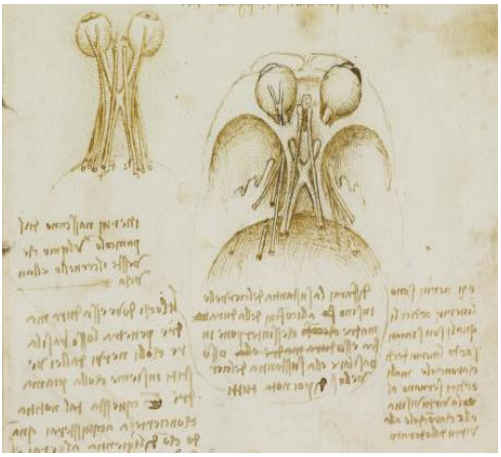

Fig. 9. Optic pathway: optic nerves, optic chiasm and olfactory bulb, in plus, the drawing includes the oculomotor, abducens and branches of the trigeminal nerve ca. 1508 (public domain)

The progresses of Leonardo da Vinci in understanding the neuroanatomy of human are comprehensively explained in the "Weimar anatomical sheet" (fig. 10) (13), a drawing from 1508 who contains two figures of the nervous system. This outstanding representation of the nervous system includes the main discoveries made by da Vinci in the field of neuroanatomy, from *sensus comunis* to cerebral ventricles, and an overall look of the layers of the head, to which he compared to the layers of an onion "If you will cut an onion through the middle, you will be able to see and enumerate all the coats or rinds, which circularly clothe the center of the onion", "Similarly, if you cut through the middle of the head of a man, you will first cut the hairs, then the scalp, then the muscular flesh and pericranium, then the cranium; and inside, the dura mater, the pia mater and the brain; then again the pia mater and dura mater and the rete mirabile and then the bone, their foundation" (14).

Fig. 10. The "Weimar anatomical sheet": ventricular system, brain and cranial nerves in pairs, ca. 1508 (public domain)

CONCLUSIONS

Leonardo da Vinci was a famous artist in his lifetime and his fame grew over time. In the field of science, through his discoveries, he is considered a pioneer in anatomy and physiology of the nervous system. He made astonishing observations in understanding neuroanatomy and neuroscience, unfortunately, those unique accomplishments did not receive a well-deserved appreciation during Renaissance Era. His papers in anatomy were not published before the period 1898-1916, so his influence on the history of anatomy was minor during the Renaissance Era. We realize the importance of his discoveries, knowing the nowadays proven truth of science, but if we look into the context in which da Vinci was, they are many reasons why he was not recognized as a neuroanatomist during his life. First of all, a court painter would not have access to academic circles that will give him the

opportunity to publish his discoveries, even for Andreas Vesalius (1514-1564) a university professor at Padua, highly respected by academic groups, it took Vesalius decades before his treatise *"De Humani Corporis Fabrica Libri Septem"* achieved recognition. Secondly, da Vinci did not study anatomy from a scientific point of view, he wanted to understand the human body more from an empirical perspective, to explain the unity of man and nature in an integrated system. His drawings were encrypted and disorganized, so he never synthesized his theories and observations into a coherent scientific paper, even nowadays, in these technologically advanced times, it took scientists many years of work to decrypt his manuscripts. We pay tribute to Leonardo work and what he represented for the humanity, a complex encyclopedic personality with a distinguish style and character who well represented the Renaissance Era.

CBCT ASSESSMENT OF MANDIBULAR BONE QUALITY AND QUANTITY IN PATIENTS WITH OSTEOPOROSIS (Abstract): Osteoporosis is characterized by weakened bones that put people at higher risk of fracture, especially in patients who have an advanced degree of damage and who follow or not treatment for osteoporosis. The **aim** of the study was to compare mandibular indices and mandibular bone density with the skeletal status investigated by osteodensitometry in patients with osteoporosis, with or without treatment. **Material and methods**: 40 patients with osteoporosis, divided into two equal groups, were evaluated by CBCT for the assessment of some mandibular indices that indicate the bone density at the cortical and cancellous bone level. The statistical analysis was performed with SPSS20.0, p=0.05. **Results**: For most of the evaluated parameters, higher values were recorded in the group of participants with osteoporosis but without treatment compared to the group of participants with osteoporosis, with treatment. The results showed a significant association between the mandibular cortical index and the type of treatment, with G1 patients presenting in a proportion of 25% the mandibular cortical index type 2, while G2 patients presented the mandibular cortical index type 2 in 58.33% of cases. In the case of G2 patients the cortical bone density values are significantly higher compared to the values corresponding to G1 patients. There are no significant differences in regard to cancellous bone density values between groups. **Conclusions:** The density of the mandibular bone is closely correlated with changes in the density and implicitly of the state of the skeleton of patients with osteoporosis, usually evaluated by bone osteodensitometry. The CBCT technique provides sufficient radiographic information that helps dentists and oral and maxillofacial surgeons to play an important role in the early diagnosis of mandibular osteoporosis**.** **Keywords:** CBCT, OSTEOPOROSIS, OSTEODENSITOMETRY.

Osteoporosis is characterized by weakened bones that put people at higher risk of fracture (1). Bone strength is a reflection of the fusion of bone quality and density are the two main characteristics. Bone density, which can be measured as grams of bone

mineral per bone area, is thought to be responsible for 60-70% of bone strength. The rate of bone turnover, mineralization, material characteristics, microarchitecture (loss of horizontal struts, loss of connectivity), and geometry are all indicators of bone quality. Age-related bone loss creates deeper resorption cavities that concentrate mechanical stress that degrades bone quality and makes those areas more prone to fracture (2, 3).

Women are disproportionately affected by osteoporosis, which causes fractures that are related to it. The number of fractures and the proportion of women with osteoporosis will rise due to current demographic trends, despite decreases in hip fracture rates. Age, low BMD, and a history of fractures are just a few of the risk factors for fracture that have been identified. The identification of women at high risk should be made easier by targeting those with multiple risk factors (3).

The mandible is an active bone and is influenced by the force of the masticatory muscles. Therefore, reducing the number of teeth causes a gradual decrease in bone mass, (4) thus creating a thinner layer of cortical bone. The mandible can be affected by systemic diseases or various drugs in terms of bone quantity and quality. It is known that after a tooth extraction, alveolar bone resorption occurs, which can be accelerated by the presence of a systemic condition such as osteoporosis. The changes that can occur in the bone tissues of the skeleton and the mandible show numerous risk factors, such as: age, race, menopause, genetic factors, various medications and family history of a disease (5).

Several studies have been conducted in the last decade that demonstrate the presence of a link between the changes that can occur in the mandibular bone and the overall BMD status of the skeleton. Some writers (6) have clearly argued that there is a substantial relationship between mandibular cortical thickness or appearance and systemic osteoporosis. Other studies have discovered no such associations, and their confidence is low (7). The World Health Organization (WHO) classified osteoporosis only based on the T score, as a decrease in BMD of less than 2.5 standard deviations below the average of a young adult of the same sex (Osteopenia Score T -1 -2.5 SD, Osteoporosis Score T-2,5 SD).

The clinicians emphasized that radiomorphometric indices and the density of the jaw bones can be calculated on imaging studies, which can serve as a diagnostic criterion of skeletal BMD, allowing them to select patients with potential BMD changes (8, 9). These radiomorphometric indices, which included the upper and lower panoramic mandibular indexes, the chin index, and the cortical mandibular index, were assessed using orthopantomography to determine the quality of the mandibular bone. Few studies have employed these indices on CBCT images to assess mandibular bone (10).

The aim of the study was to compare mandibular indices and mandibular bone density investigated by osteodensitometry in patients with osteoporosis, with or without treatment.

MATERIAL AND METHODS

The study was carried out in the Medimagis Clinique of oral and Maxillo-Facial Radiology, Iasi. In this study, 40 patients with osteoporosis were included, who presented for CBCT investigations to plan the surgical treatment. Patients signed an informed consent prior to their inclusion

in the study. The study was approved by the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy, Iasi (No. 281/5.03.2023).

The inclusion criteria of patients in this study were: only women before menopause, aged between 40 and 80 years, diagnosed with osteoporosis and different classes of mandibular edentulousness. Exclusion criteria were local conditions affecting the mandible, postmenopausal status and other secondary causes of osteoporosis. The participants were equally divided into two groups: group 1 - participants with treatment for osteoporosis (G1), group 2 - participant without treatment for osteoporosis (G2).

All these patients presented clinical observation sheets, from which additional information was extracted regarding the status of the disease and its complications (hemoleucogram, CTX). An anthropometric assessment was also performed which included data on height, weight and abdominal circumference.

CBCT examination of the mandible

This research is part of a large study related to the radiological determination of bone characteristics in patients with general pathologies. This research is part of a large study related to the radiological determination of bone characteristics in patients with general pathologies. The working technique is described in detail in the study carried out by Nemtoi *et al.* (2019)(11). The Planmeca Promax 3D Mid (Planmeca OY, Helsinki, Finland) CBCT equipment was utilized to do the scan that was carried out with a FOV of 100x60 mm with the following exposure parameters: 85-90 kV, 11-12 mA, 12,02 seconds, voxel size of 200 mm, and 578 DAP (mGyxcm2). Romexis 4.4.0 software (Planmeca, Helsinki, Finland) was used to produce the initial and final reconstructions. CBCT reconstructions with a thickness of 1 mm and a distance of 1 mm were used to create sagittal and panoramic sections.

Mandibular bone analysis, quantitative and qualitative

Radiomorphometric indices tailored FOR CBCT images were utilized for quantitative and qualitative examination of the mandible according to Ledgerton's categorization (Ledgerton *et al*, 1999) the following indices were measured on CBCT images:

1) CBCT upper mandibular index, which represents the ratio between the thickness of the lower cortex and the distance from the level of the upper edge of the chin foramen to the lower edge of the mandible.

2) CBCT lower mandibular index, which represents the ratio between the lower cortical thickness and the distance from the lower edge of the chin foramen to the lower edge of the mandible.

3) The CBCT chin index, which represents the thickness of the lower cortex of the mandible, near the chin foramen.

4) CBCT mandibular cortical index, which is classified as follows:

✓ Type 1: the endosteal margin of the basilar bone cortex appears smooth and regular.

✓ Type 2: the endosteal edge of the basilar bone cortex presents semilunar defects or 1-2 layers of cortical debris.

✓ Type 3: the endosteal margin shows numerous (> 3) cortical remnants and is obviously porous.

In addition, mean bone density was estimated for the regions of interest for qualitative analysis.

A B C

Fig. 1. CBCT aspect of measurements made on sagittal sections. A. The distance from the level of the upper border of the chin foramen (S) to the lower border of the mandible. B. The distance from the lower edge of the chin foramen (i) to the lower edge of the mandible. C. G represents the thickness of the lower cortex of the mandible, near the chin foramen (Medimagis collection)

These measures were taken from the sagittal (fig. 2) and panoramic (fig. 3) reconstructions produced by the CBCT examination.

A radiologist with long practice in oral and maxillofacial radiology used Romexis 4.4.0 software (Planmeca, Helsinki, Finland) to do all measurements.

Statistical analysis

Data were analyzed with a statistical software package (*SPSS* version 20.0, SPSS Inc, Chicago, IL). Statistical tests were used to measure the differences between mandibular bone quality, bone mineral density at the level of the mandible: frequencies (%), average values, minimum and maximum values, ANOVA and Kruskal-Wallis test. Comparisons were made between groups. Statistical significance was established at p=0.05.

RESULTS

Both the right lower mandibular index (F=0.0018, p=0.892) and the left lower mandibular index (F=0.323, p=0.5729) show comparable values without significant differences in the case of G2 patients compared to G1 patients (tab. I).

TABLE I.

Statistical indicators for IMI $_{right}$ /$_{left}$ values. *vs.* groups

	Group	Av. IMI	Average		SD	SE	Min	Max	Q25	Median	Q75
			-95%	+95%							
IMI right	G1	0.45	0.29	0.62	0.31	0.08	0.11	0.98	0.14	0.40	0.78
	G2	0.44	0.34	0.54	0.24	0.05	0.18	0.90	0.23	0.43	0.61
IMI left	G1	0.44	0.29	0.59	0.29	0.07	0.12	0.89	0.15	0.38	0.74
	G2	0.48	0.39	0.58	0.22	0.04	0.20	0.91	0.27	0.46	0.64

The study of the values of the right upper mandibular index and the left upper mandibular index demonstrated the absence of significant differences depending on the group, the average values being in the case of G2 patients of IMS right → 0.50±0.32 SD and IMS left → 0.53±0.31 SD, and in the case of G1 patients, the average values were IMS right → 0.57±0.27 SD and IMS left → 0.59±0.25 SD (tab. II).

TABLE II.

Statistical indicators for IMS $_{right\ /\ left}$ values *vs.* groups

	Groups	Av. IMS	Average		SD	SE	Min	Max	Q25	Median	Q75
			-95%	+95%							
IMS right	G1	0.50	0.33	0.67	0.32	0.08	0.14	0.99	0.17	0.44	0.80
	G2	0.57	0.46	0.69	0.27	0.05	0.19	0.98	0.29	0.57	0.80
IMS left	G1	0.53	0.37	0.70	0.31	0.08	0.17	0.98	0.21	0.46	0.82
	G2	0.59	0.48	0.69	0.25	0.05	0.21	0.98	0.33	0.63	0.76

The analysis of the values of the right chin index according to the type of treatment, demonstrates significant values (F=6.67, higher for patients with G2 (2.47±0.8 SD) compared to patients with G1 (1.67±0.8 SD).

The values of the left chin index are significantly (F=6.95, p=0.0121, 95% CI) higher in patients with G2 (1.8±1.13 SD) compared to the values recorded in patients with G1 (2.58±0.75 SD) (tab. III).

The study of the degree of association between the mandibular cortical index and the type of treatment demonstrated the presence of a significant correlation, with G1 patients presenting in a proportion of 25% the mandibular cortical index type 2, while G2 patients presented the mandibular cortical index type 2 in 58.33% of cases (r=-0.298, χ^2=8.46, p=0.0145, 95% CI) (fig. 4, tab. IV).

TABLE III.

Statistical indicators for IMn $_{right/left}$ values *vs.* groups

	Groups	Av. IMn	Average		SD	SE	Min	Max	Q25	Median	Q75
			-95%	+95%							
IMn right	G1	1.67	1.05	2.29	1.17	0.29	0.20	4.20	0.65	1.60	2.55
	G2	2.47	2.13	2.81	0.80	0.16	1.20	3.50	1.80	2.70	3.25
IMn left	G1	1.80	1.20	2.40	1.13	0.28	0.30	3.80	0.80	1.90	2.70
	G2	2.58	2.27	2.90	0.75	0.15	1.40	3.80	1.90	2.80	3.25

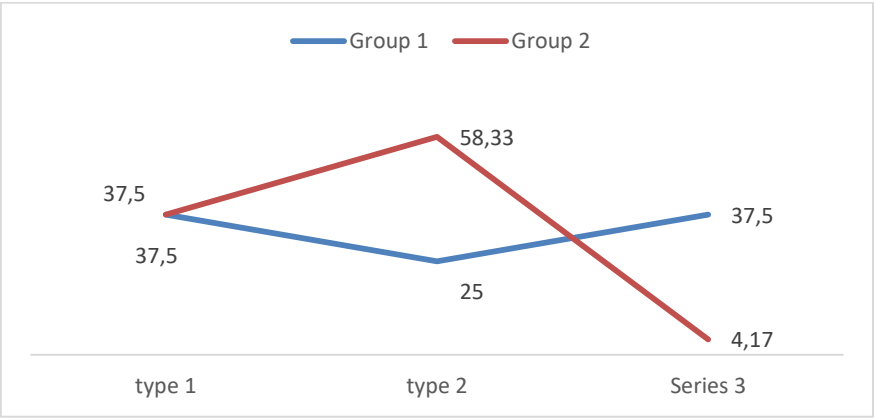

Fig. 4. Distribution of cases according to mandibular cortical index *vs.* groups

TABLE IV.

The estimated parameters in testing the association of the mandibular cortical index *vs.* groups

df=2	Chi-square χ^2	p 95% CI
Pearson Chi-square - χ^2	8.465609	0.01451
M-L Chi-square	8.839532	0.01204
Correlation coefficient (Spearman Rank R)	-0.298507	0.23613

The analysis of the edentulous region according to type of treatment reveals the fact that in the case of G1patients the edentulous region is frequently found anteriorly, while in the case of G2 patients the edentulous region is found in the posterior region (fig. 5). These results demonstrate the significant association between type of osteoporosis treatment and the edentulous region (r=0.793, χ^2=8.83, p=0.00221, 95%CI) (tab. V).

The analysis highlighted the fact that in the case of G2 patients the cortical bone density values (704.38±352.1 SD) are significantly higher (F=4.38, p=0.0430, 95% CI) compared to the values corresponding to G1 patients (896.86±230.8 SD).

In the case of G2 patients, the cancellous bone density values (738.96±259 SD) do not show significant differences (F=3.607, p=0.065, 95% CI) compared to the values corresponding to G1 patients (562±359 SD). Since the distribution of values is not normal in this case, the results of the analysis considered the Kruskal-Wallis test, which is specific to these types of data (tab. VI).

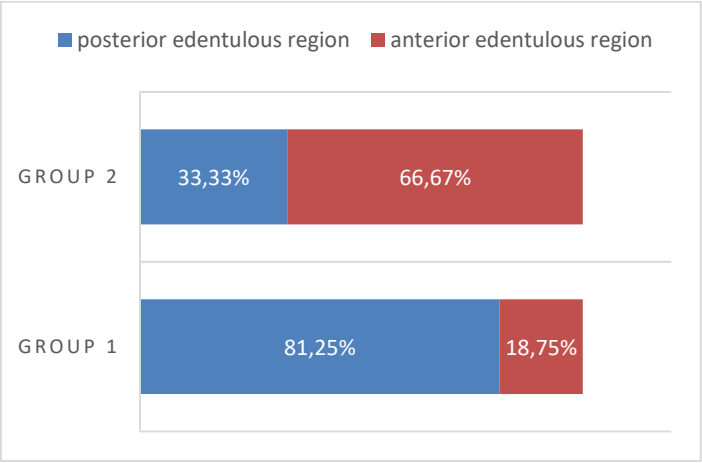

Fig. 5. Evaluation of the localization of mandibular edentation according to groups

DISSCUSION

This study investigated the mandibular bone by applying two different radiological techniques whose results were compared. His aim was to assess the quality and quantity of mandibular bone in a population of treated and untreated patients with osteoporosis, as the quality and quantity of mandibular bone is of particular importance in certain dental treatments.

Bones differ in anatomical structure, with a different distribution of trabecular and cortical bone. Trabecular bone has a larger surface area and responds more rapidly to metabolic changes than cortical bone (12). The changes that can occur in the thickness of the mandibular cortex and the occurrence of systemic osteoporosis at the level of the skeleton have been studied by numerous researchers (6).

Preoperative CBCT measurements will give the practitioner useful information on

bone quality and amount. Radiomorphometric indices developed for CBCT pictures were utilized for quantitative and qualitative examination of the mandible, and the findings obtained were significant for the study's goal.

In the case of G2 patients compared to G1 patients, the lower mandibular index reveals comparable values with no significant changes. The upper mandibular index showed no significant variations based on the group, with average values in all six groups.

The examination of the values of the right chin index based on treatment type reveals that patients with G2 had significantly greater values for both sides than patients with G1.

The findings revealed a substantial relationship between the mandibular cortex index and the kind of therapy, with G1 patients exhibiting the mandibular cortical index type 2 in 25% of instances and G2 patients exhibiting the mandibular cortical index type 2 in 58.33% of cases.

The examination of the edentulous region based on treatment type indicates that in the case of G1 patients, the edentulous region is usually located anteriorly, but in the case of G2 patients, the edentulous region is frequently found posteriorly. In our investigation, we discovered a strong relationship between the kind of osteoporosis therapy and the edentulous area.

Cortical bone density readings in G2 patients are substantially greater than values in G1 patients. There are no statistically significant differences in cancellous bone density values across groups.

The fact that the parameters obtained in the group of patients receiving osteoporosis therapy were lower than in the group of participants with osteoporosis but not receiving treatment may be explained through the lens of the kind of drug supplied and the course of osteoporosis. Several studies have been conducted to demonstrate the function of antiresorptive medicine in enhancing bone density

Thus, Bouxsein *et al.* (13) discovered increases in bone mineral density following raloxifene therapy, as well as a substantial reduction in fracture risk. According to Nils Heim *et al.*, (14) the impacts on bone density and microarchitecture are restricted to cortical bone and not cancellous bone. This is because bone remodeling is dependent on a balance of osteoclastic (bone-resorbing) and osteoblastic (bone-formation) activity. Antiresorptive drugs inhibit osteoclasts and reduce bone resorption by binding to active areas of bone remodeling. In the absence of therapy, bone density drops by 1.8% in the first 5 years after start, and the average N-telopeptide of cross-linked collagen type 1 is reduced by 70% below baseline, according to Bone *et al.*

The group sizes were one of the stud's limitations. More research with a bigger sample size, as well as an evaluation of the association between CBCT findings and BMD of other bone locations in osteoporosis patients, are required.

CONCLUSIONS

CBCT is a 3D type of imaging method used in dentistry. The CBCT approach gives adequate radiographic information to assist dentists and oral and maxillofacial surgeons in the early detection of mandibular osteoporosis. Furthermore, this study reveals that the density of mandibular bone is directly connected to changes in the density and, implicitly, the status of the skeleton in individuals with osteoporosis, as measured by bone osteodensitometry.

CONFLICT OF INTEREST AND FUNDING

INNOVATIVE SYNTHESIS OF ZINC AND SELENIUM COMPLEXES WITH GALLIC ACID: EXPLORING THEIR ANTIOXIDANT POTENTIAL (Abstract): Polyphenols are naturally occurring compounds found largely in fruits, vegetables, cereals and beverages. Fruits like grapes, apple, pear, cherries and berries contain up to 200–300 mg polyphenols per 100 grams fresh weight. Among these compounds, gallic acid, (GA), a trihydroxybenzoic acid, stands out for its selective cytotoxicity against various tumor cell lines. This study focuses on the synthesis and analysis of a new complex of Zn(II) with GA, but also Se(IV) with gallic acid, exploring its comparative antioxidant potential. **Materials and methods:** The complex, synthesized in a 1:2 molar ratio of GA to zinc acetate dihydrate, respectively sodium selenite pentahydrate, showed various promising therapeutic roles in vitro. GA and zinc both possess antioxidant properties, and their coordination in the complex increases these attributes depending on the concentration. **Results:** GA, known for its powerful antioxidant effects, outperforms popular antioxidants like ascorbic acid in various tests. The study evaluates the ability of GA to remove reactive species, showing its superior efficiency. In addition, GA and its ester derivatives demonstrate protective effects against lipid peroxidation, a important process in cellular damage. **Conclusions:** The synthesized Zn(II) complex, with its structure-activity relationship suggesting Zn(O4) coordination, opens avenues for understanding its antioxidant potential. Overall, this research reveals the multifaceted pharmacological potential of GA and its complexes, providing insights into their antioxidant effects. **Keywords:** METAL-ION-COMPLEX, GALLIC ACID-ZINC-COMPLEX, ANTIOXIDANT CAPACITIES.

Polyphenols, also known as phenolics, are ubiquitous in nature and represent a structurally diverse group of compounds, particularly prevalent in plant species (1, 2). Among them, condensed tannins, the most abundant polyphenols, are found across various plant families, including lower organisms such as mushrooms (3-6).

Certain polyphenols, such as phytoalexins produced by plants in response to pathogen intrusion, exhibit a hypersensitive reaction (7-10).

The presence of polyphenols can contribute to environmental contamination in proximity to processing facilities engaged in the production of olive oil, coffee, paper, and within the carpet industry. Conversely, numerous polyphenols are renowned for their antioxidative (11, 12), anti-inflammatory (13), and anticancer properties (14, 15), warranting attention in the realm of drug development, particularly for combating cancer (16, 17, 18, 19).

One prominent polyphenol of note is GA, (3,4,5-trihydroxybenzoic acid) (fig. 1), which holds significant relevance due to its selective cytotoxicity against various tumor cell lines.

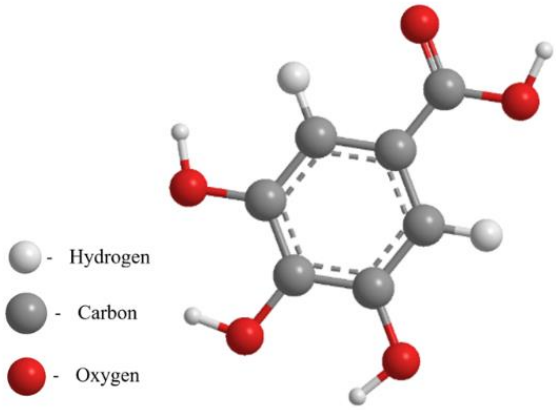

Fig. 1. 3D rendering of the GA molecule (made by using Chem3D)

GA is an organic compound belonging to the class of polyphenols. It is marketed as a crystalline powder, either white or pale yellow. It is a trihydroxybenzoic acid with a benzene ring in its structure, to which a carboxylic group providing acidity to the molecule (-COOH) is attached, along with three hydroxyl groups (-OH) located at positions 3, 4, and 5 of the ring (20, 21).

GA is an endogenous plant polyphenol abundant in tea, grapes, berries, and other fruits, as well as in certain hardwood species like oak (*Quercus robur*) and chestnut (*Castanea sativa* L.). It manifests as yellowish-white crystals, possesses a molecular mass of 170.12 g/mol, a melting point of 250°C, and exhibits water solubility of 1.1% at 20°C (22, 23).

Known for its profound impact on several pharmacological and biochemical pathways, GA demonstrates potent antioxidant, anti-inflammatory, antimutagenic, and anticancer properties (24, 25, 26). Moreover, GA exhibits pro-oxidant characteristics in a concentration-dependent manner in the presence of metal ions, a trait that has been identified as an inducer of apoptosis in cancer cell lines (27). Studies have also confirmed the protective role of GA against chemically induced carcinogenesis (28, 29).

MATERIALS AND METHODS

For the synthesis and analysis of the studied complex we have used the follow-

ing reagents and equipment:

- Polyphenol (GA) –analytical grade purity, purchased from Sigma-Aldrich;
- Metalic ion salts (Zinc acetate, Sodium selenite) Sigma-Aldrich;
- Solvents (Distilled water, Methanol, Absolute ethanol, 96% Ethanol) (Sigma-Aldrich);
- Magnetic stirring plate;
- Laboratory grade glassware (Erlenmeyer flasks, beakers, magnet for stirring, thermometer);
- Filter paper;
- Analytical balance Mettler (Mettler Toledo, Greifensee, Switzerland);
- Magnetic stirring FALC-30ST;
- spectrophotometer Specord® 210 PLUS

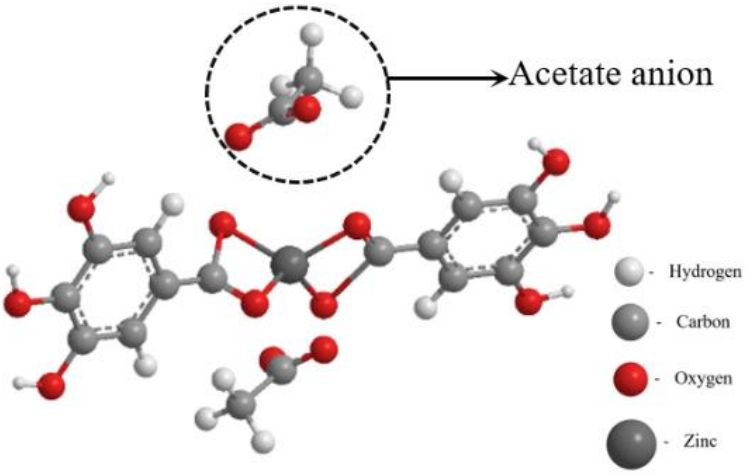

Fig. 2. 3D rendering of the synthesized Gallic acid-Zn(II) complex (made by using Chem3D)

INSTRUMENTATION

Instrumentation for the structural characterization of the formed complex involved Fourier-transform infrared spectroscopy (FTIR). The FTIR spectra were acquired using an FT-IR Bruker Vertex 70 Spectrophotometer in reflexional mode with the attenuated total reflectance (ATR) technique. Spectral analysis was conducted at a scan rate of 40/s within the range of 4000 cm-1 to 380 cm^{-1}, using approximately 1 mg of sample.

A ^{1}H NMR spectrum reveals the chemical shifts corresponding to various protons within the tested samples (30, 31).

The Nuclear Magnetic Resonance spectra ^{1}H-RMN, were registered using a Bruker Vance III apparatus, at 500 MHz in deuterated dimethyl sulfoxide (DMSO-d_6). The displaced chemical signals present in the registered spectra, were represented using δ values in parts per million (ppm), and the coupling constancies J in Hz.

Synthesis of the gallic acid and Zinc(II) complex

The complex was synthesized using zinc acetate dihydrate and GA in a 1 :2 molar ratio, our study has followed this method with slight alterations. The synthesis started by weighing the reagents and dissolving 376.3 mg of GA monohydrate

and 219.51 mg of zinc acetate dihydrate separately in 5 mL of methanol each. After this, the solutions were gradually stirred using a magnetic stirring plate. The complex, Fig. 2, formed as a white, almost milky gelatinous precipitate, which was separated by filtration.

The resulting precipitate was washed multiple times with a 50% methanol solution, dried and stored at standard room temperature in air-tight glass vials.

Synthesis of the gallic acid and Se(VI) complex

The complex was synthesized using sodium selenite and GA, our study has followed the method described in the literature with slight alterations (32). The synthesis started by weighing the reagents and dissolving 376 mg of GA monohydrate and 263 mg of sodium selenite pentahydrate separately in 5 mL of methanol each. After this, the solutions were gradually stirred using a magnetic stirring plate. The complex, formed as a dark grey precipitate which was separated by filtration.

The resulting precipitate was washed multiple times with a 50% methanol solution, dried and stored at standard room temperature in air-tight glass vials.

Zinc(II) exhibits a preferential tetrahedral coordination but can also adopt higher coordination geometries, such as octahedral. It tends to favor ligands that form relatively weak bonds, making zinc less prone to forming highly stable complexes with strongly chelating ligands compared to other transition metals. Zinc complexes are relatively stable and find applications in various pharmaceutical and industrial settings. Due to their moderate stability, zinc complexes are ideal for applications requiring controlled release of the ligand (33, 34).

In the complex with zinc(II) ions, bonds are formed with GA molecules. These bonds can be coordinative, where the oxygen atoms of the functional groups in GA bind to zinc ions. Both zinc and GA possess antioxidant properties. GA, among numerous plant-derived polyphenols, possesses both antioxidative and antidiabetic pharmacological potential (35, 36).

Antioxidant activity

The DPPH scavenging activity of the complex was measured using a modified version of a previously described method by Sanni O *et al.* (37). The assay mixture comprised 75 µl of various concentrations (ranging from 3.75 to 60 µM in the reaction mixture) of the complex, along with its precursor GA, zinc(II) acetate, sodium selenite (IV), or standards such as ascorbic acid, or their respective solvents (control). Additionally, 37.5 µl of a 0.3 mM DPPH solution was added to the mixture in a 96-well plate. Following a 30 minutes incubation period in the dark, absorbance readings were taken at 517 nm using a Specord® 210 PLUS spectrophotometer. Sample blank or sample solvent was utilized as the blank. The following formula was employed to calculate the percentage of DPPH radical scavenging activity:

$$\% \text{ inhibition} = 100 \times (A_{control} - A_{final}) / A_{control}$$

where:

$A_{control}$ is the absorbance of DPPH before adding the GA or ots complexes

A_{final} is the absorbance of the DPPH mixture after adding the GA or its complexes and incubating in a dark place.

The evaluation of the antiradical potential of antioxidants commonly employs the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay, where DPPH, a stable free radical

with an absorbance band at 517 nm, undergoes reduction upon interaction with an antiradical compound (38, 39). The statistical evaluation was performed by determining the mean values of five readings for each sample and for each concentration used. The data included in the graphs represent the average ± the standard deviation.

RESULTS AND DISCUSSION

In our study, the most important assessed parameter was the nature of the solvent used for synthesis. It can be observed in Figure 3, that the superior yield was obtained when using methanol as the solvent for the complexation reactions. The polarity of the solvent and its capacity to form hydrogen bonds has an impact on the interactions between the metallic ions and the ligand used.

The confirmation of complex formation was achieved through ^{1}H-NMR spectroscopy in DMSO-d_6. The absence of the signal corresponding to the proton of the carboxylic group is observed at 13-12 ppm. The region between 10-9 ppm for both complexes undergoes slight modifications, with no change in the region of aromatic protons.

The structure of GA was confirmed through the ^{1}H-NMR proton spectrum in DMSO-d_6. The region at 13-12 ppm corresponds to the proton of the carboxylic group (-COOH), being the most shielded. The region of 10-9 ppm corresponds to the protons of the hydroxyl groups (-OH), and the region of 7-6.7 ppm is attributed to the aromatic protons in the benzene ring GA.

The characteristic bands of the phenolic hydroxyl group were observed in the FTIR absorption spectrum of GA and its complex in the range of 3200-3400 cm^{-1}, representing stretching vibrations due to intramolecular hydrogen bonds.

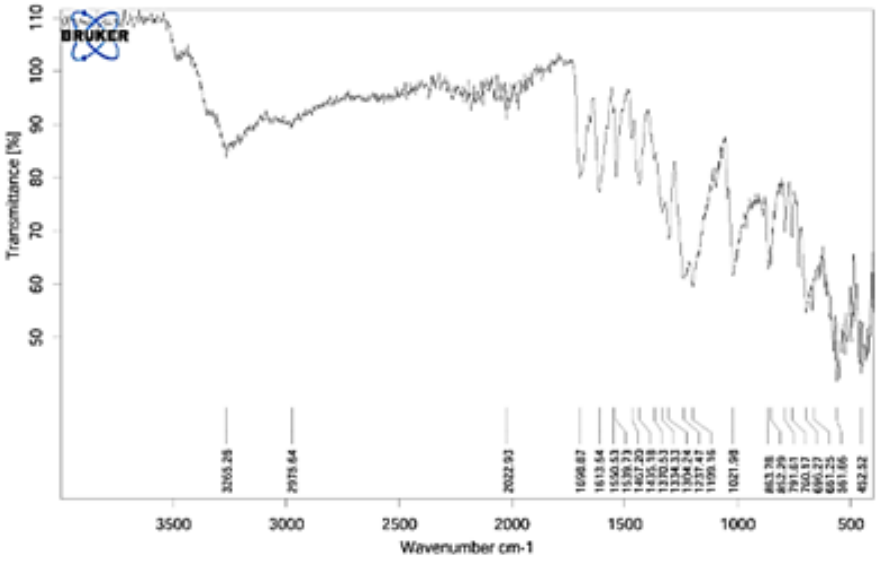

Fig. 7. FTIR absorption spectrum of GA

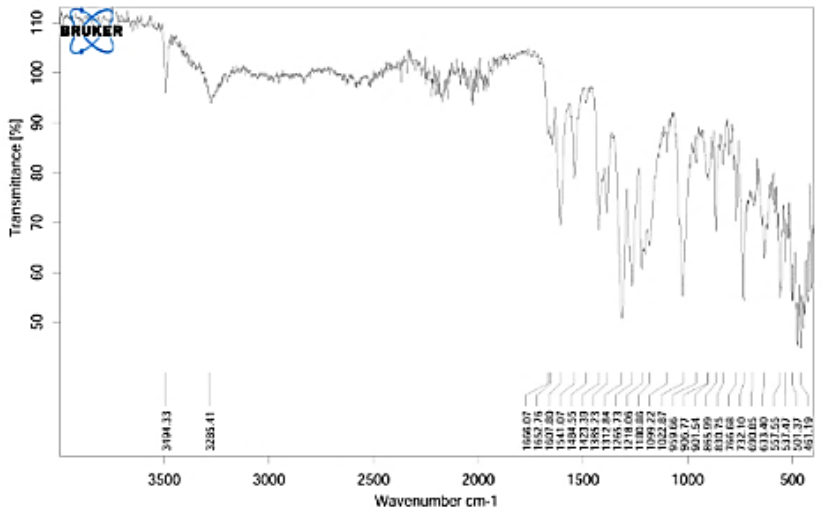

Fig. 8. FTIR absorption spectrum of gallic acid-Zn(II)

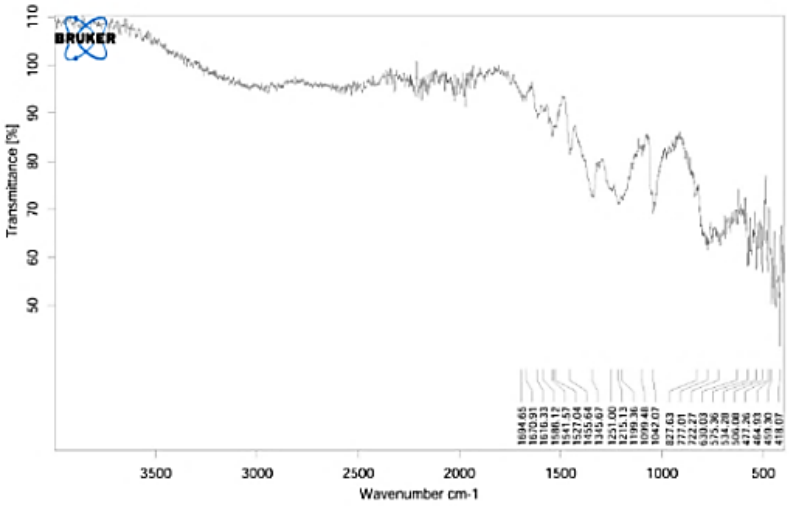

Fig. 9. FTIR absorption spectrum of gallic acid-Se(IV)

The presence and structure of the gallic acid-Zn(II) complex is confirmed by the presence of bands observed in GA at 1378 and 1306 cm^{-1} and in its complex with zinc acetate at 1374, 1336, and 1307 cm^{-1}, representing specific bending vibrations of aromatic nuclei. The band at 3085-3024 cm^{-1} is characteristic of the stretching vibration of the C-H bond in the aromatic ring. In the ranges of 2995-2863 cm^{-1} and 1648-1582 cm^{-1}, bands appear due to stretching vibrations of –CH3 groups and the >C=C< bond, respectively. Bending vibrations of the aromatic CH bond and the –CH3 group occur at

1458 cm^{-1} and 1357 cm^{-1}, respectively. Bands in the ranges of 1247-1000 cm^{-1} and 567-501 cm^{-1} are attributed to in-plane and out-of-plane deformation vibrations of the aromatic ring.

The presence and structure of the gallic acid-Se(IV) complex is confirmed by the presence of bands observed in GA at 1378 and 1306 cm^{-1} and in its complex with sodium selenite at 1345, 1251, and 1215 cm^{-1}, representing specific bending vibrations of aromatic nuclei. The band at 3085-3024 cm^{-1} is characteristic of the stretching vibration of the C-H bond in the aromatic ring, and in the range of 1648-1582 cm^{-1}, bands are present due to the >C=C< bond. Bending vibrations of the aromatic CH bond occur at 1458 cm^{-1} and 1357 cm^{-1}, respectively. Bands in the ranges of 1247-1000 cm^{-1} and 567-501 cm^{-1} are attributed to in-plane and out-of-plane deformation vibrations of the aromatic ring. The confirmation of complex formation can also be supported by the absence of vibration bands at 3263 cm^{-1} corresponding to the -OH groups.

The complex combinations of GA with zinc(II), selenium(IV), as well as free GA, were subjected to examination, and their antioxidant activity was tested through recorded absorbance.

	0,15 mg/mL	0,3 mg/mL	0,6 mg/mL	1,2 mg/mL	2,4 mg/mL
Gallic acid	6,789458958	12,3777927	17,45687893	20,5060345	22,15477735
Gallic acid-Zn(II)	5,965881712	10,59885661	12,03189585	15,04001807	21,0034562
Gallic acid-Se(IV)	4,67423842	10,60146518	15,45787991	18,84682504	22,23781714

Fig. 10. DPPH• % inhibition of gallic acid and its complexes with Zn(II) and Se(IV)

GA complexed with selenium ions exhibited the highest antioxidant activity at the highest concentration. However, it can be observed that at different concentrations, GA demonstrates stronger antioxidant action. The action also depends on the molar ratio used in synthesis, in this case, GA: zinc salt = 1:2. Referring to the structure of GA, the newly formed bonds resulted in a decreased antioxidant activity.

Comparing our results to the literature, the findings were confirmed by Samy M. and colleagues (40), who also obtained lower absorbance for free GA at maximum concentration and higher absorbance for the gallic acid-selenium(IV) complex. In another study conducted by Denice M. Motloung and colleagues (41), the gallic acid-zinc(II) complex recorded a higher inhibition percentage at concentrations of 15, 30, and 60 μM compared to free GA and ascorbic acid.

Under these conditions, chelating GA with selenium(IV) enhances the antioxidant activity of the polyphenolic acid, depending on the molar ratio, solvent, and the

concentration of the tested complex. The antioxidant properties of zinc acetate, used for synthesizing the complex with GA, were also tested, but the results obtained were very small, almost irrelevant for its use as an antioxidant.

An important aspect is that these metal ions can be used in combination with polyphenols, improving the antioxidant activity of the complex.

Studies by Abdelwahed *et al* (42) reveal that GA and 1,2,3,4,6-pentagalloylglucose (PGA) employ a hydrogen-donating mechanism to scavenge DPPH radicals, proving more effective than Vitamin E. The antioxidant activity order, ranks GA above caffeic acid, ascorbic acid, Trolox, sinapinic acid, and isoeugenol (43).

Beyond the DPPH assay, GA excels as a potent antioxidant in various assays such as Trolox equivalent antioxidant capacity, total radical-trapping antioxidant parameter (TRAP), photochemiluminescence (PCL), and ferric reducing ability of plasma (FRAP). It outperforms popular antioxidants like ascorbic acid, Trolox, and uric acid. Computational studies further confirm GA's superior antioxidant efficiency compared to various counterparts. At a concentration of 4.17 mM, GA exhibits significant scavenging effects on DPPH and H_2O_2 radicals. GA and n-alkyl gallates effectively scavenge other reactive species, HOCl, at low concentrations, protecting a1-antiproteinase and reducing ox brain phospholipid peroxidation (44, 45).

Moreover, GA and its ester derivatives showcase antioxidant capacity against various reactive oxygen and nitrogen species, including peroxyl, azide, and hydroperoxyl radicals (46, 47).

CONCLUSIONS

The complex produced by the combination of zinc acetate and GA resulted in good yield when methanol was used as solvent and NaOH as co-regulator. The same mechanism was in the case of the reaction between GA and sodium selenite.

Various modern techniques have confirmed the formation of complex combinations. Moreover, the antioxidant capacity did not show very large variations in the case of the tested compounds, the activity being dependent on the concentration of the sample to be analyzed.

It can be concluded that the antioxidant action is much better for the complex with zinc or selenium ions compared to pure salt.

Other antioxidant tests are needed to describe a more complex mechanism of the complex combination.

THE PREVALENCE OF IMPLANT SUCCESS VERSUS FAILURE IN A ROMANIAN SAMPLE POPULATION. A RETROSPECTIVE STUDY (Abstract**):** Research has revealed that patterns of dental implant failure often occur in groups within individuals and are linked to various factors such as dietary preferences, intake of cold/hot beverages. **Materials and methods**: this research was to investigate the potential correlation between changes in the frequency of dental implant loss due to consumption of hot/cold beverages and dietary habits. Information was gathered from the patient records of individuals seeking implant-prosthetic treatments at the "M. Kogălniceanu" Dental Education Base. **Results:** Out of the examined database, 47 cases were chosen based on the selection criteria. The average age of the study group was 41.6 ± 5.051 years (with a minimum age of 27 years and a maximum age of 49 years). Over half of the participants were male. It has been noted that the intake of solid foods is linked to dental implant loss, showing a positive but moderate level of association (r=0.573). In terms of the impact of consuming hot beverages on the lifespan of implants, the statistical analysis suggests a positive relationship between the two factors, albeit with a relatively weak correlation (r=0.382). **Conclusions:** It is recommended that additional research be conducted to identify the possible risk of implant failure associated with the regular intake of extremely hot beverages, which patients rarely report. **Keywords:** DENTAL IMPLANT, DIETARY HABITS, TEMPERATURE.

INTRODUCTION

In recent years, technological advancements and research in the field of biomechanics have brought about a series of innovations in the realm of implant-prosthetic restorations (1). From new materials and computer-aided design techniques to improvements in implant placement and integration, these new discoveries have revolutionized the way these restorations are planned, fabricated, and implemented (2, 3).

The introduction of advancements in the field of biomechanics applied to implant-prosthetic restorations represents an essential approach to understanding the complexity of interactions between implants, bone, soft tissues, and restoration as a whole (4, 5).

The biomechanics of implant-prosthetic restorations involves the study of forces and stresses acting on these structures during normal oral cavity function (6). It is crucial to understand how these forces are distributed and how they can be managed to prevent restoration failures and ensure optimal long-term functionality (7, 8). From the initial conception of a treatment

plan to the completion of the restoration, bio-mechanical aspects must be considered at every stage of the process (9-11).

Nevertheless, there are certain drawbacks to this treatment approach. Various studies have shown that dental implants have failure rates anywhere from 1% to 19% (12, 13). The abutment connection time determined whether the failure occurred before or after functional loading. In the former case, the failure occurred before occlusal loading or the first removal of the provisional restoration, while in the latter case, the failure occurred after (14).

A dental implant is considered to have failed early if osseointegration cannot be achieved, and a dental implant is considered to have failed late if either osseointegration or function cannot be maintained (15). In early failure, there are just biologic difficulties (16), but in late failure, there could be mechanical as well as biologic issues. Resorption of both soft and hard tissues is a common symptom of peri-implantitis, which can lead to biologic problems (17, 18). Inadequate implant loading design is a potential source of mechanical problems, which can cause the implant body, screw body, or implant suprastructure to fracture (19).

The aim of this study was to find the existence of a link, between the increase/decrease the frequency of losing dental implants because of the intake of hot/cold beverages and dietary preferences.

Thus, patients, doctors, and prosthodontists/restorative experts may all benefit from a better understanding of the causes of late dental implant failure in order to better anticipate treatment results and avoid disagreements.

MATERIALS AND METHODS

The retrospective study aimed at detecting correlations between dental implant loss and the presence of certain risk factors. Data were collected from the patient records of those who presented at the "M. Kogalniceanu" Dental Education Base for implant-prosthetic treatments.

The selection criteria for the clinical cases were as follows: patients who lost one or more implants due to peri-implantitis, without associated systemic diseases, without dental trauma, without periodontal disease, non-smokers, and patients aged between 25 and 50 years.

From the patient's record, data were extracted regarding the patient's age, gender, origin environment, number of implants lost, their location, the type of prosthesis made on these implants, the duration of their survival on the arch, the type of opposing arch, the type of diet (consistency), as well as the consumption of hot beverages, factors that can affect the integrity and persistence on the arch of the implants.

To achieve the purpose of this study, associations between the number of implants lost and the type of diet and beverages consumed were analyzed.

The statistical analysis was conducted using *SPSS 26.0* (IBM, NY, USA). The results of the statistical analysis were presented in the form of mean values and frequencies. Statistical differences between genders and origin environments were analyzed. Pearson's correlation coefficient was used to analyze the correlations between variables. The level of statistical significance was set at $p=0.05$.

RESULTS

From the analyzed database, 47 cases were selected that met the selection criteria. The study group had an average age of 41.6±5.051 (min. age - 27 years, max. age = 49 years). More than half of the participants were males (62.2%), with 82.2% of participants coming from an urban environment (tab. I).

TABLE I.
Demographic characteristics of the study group

	No	%
Age	41.6±5.051 (min. age - 27 years old, max. age = 49 years old)	
Sex		
Females	17	37.8
Males	28	62.2
Place of residence		
Urban Area	37	82.2
Rural	8	17.8

In Table 2, information is presented regarding the distribution of cases based on demographic characteristics and the status of the lost implants. 63.8% of cases lost 2 implants, with more than half of these having a survival period on the arch of 6-10 years (59.6%). 61.7% of the implants were overdenture with removable prostheses, the implants being placed predominantly in the lateral areas. The type of opposing arch was 40% natural or mixed (31.9%). The majority of lost implants were recorded in male subjects from urban areas, many of the implants having a survival period on the arch of 6-10 years.

TABLE II.
Distribution of cases

			Gender		Residence	
	No.	**%**	**Female**	**Male**	**Urban**	**Rural**
Number of implants						
1 implant	17	36.2	35.3%	64.7%	88.2%	11.8%
2 implants	30	63.8	36.7%	63.3%	80.0%	20.0%
p			0.591		0.385	
Number of years since implantation						
<5 years	11	23.4	45.5%	54.5%	90.9%	9.1%
6-10 years	28	59.6	28.6%	71.4%	85.7%	14.3%
>10 years	8	17.0	50.0%	50.0%	62.5%	37.5%
p			0.412		0.222	
Type of denture						
Dental bridges	18	38.3	90.9%	9.1%	88.9%	11.1%
Removable denture	29	61.7	85.7%	14.3%	79.3%	20.7%
p			0.107		0.334	
Type of opposing arch						
natural arch	19	40.4	26.3%	73.7%	84.2%	15.8%
mixed arch	15	31.9	46.7%	53.3%	86.7%	13.3%
artificial arch	13	27.7	38.5%	61.5%	76.9%	23.1%
p			0.462		0.778	
Implant location						
frontal area	17	36.2	35.3%	64.7%	82.4%	17.6%
lateral premolar area	15	31.9	53.3%	46.7%	80.0%	20.0%
Lateral molar area	15	31.9	20.0%	80.0%	86.7%	13.3%
p			0.164		0.885	

The statistical analysis results of the associations between the number of lost implants and the dietary preferences of participants are presented in table III. It is observed that the consumption of foods with a hard consistency is associated with the loss of dental implants, with a positive but moderate intensity of association (r=0.573); however, the differences in the number of implants lost are statistically insignificant (p=0.840). Regarding the effect of consuming hot beverages on the survival period of implants, the statistical analysis indicates a positive association between the two variables, though the correlation is relatively weak (r=0.382).

TABLE III.
Correlations between number of lost implants and dietary preferences

	No of lost implants		p	r
	1 implant	2 implants		
Dietary preferences				
Soft food	5.9%	3.3%	0.840	0.573
Hard food	82.4%	80.0%		
Both	11.8%	16.7%		
Beverage preferences				
Cold beverages	23.5%	13.3%	0.306	0.382
Hot beverages	76.5%	86.7%		
Frequency of hard food consumption				
daily	88.2%	90.0%	0.603	0.854
occasionally	11.8%	10.0%		
Frequency of hot/cold beverage consumption				
daily	76.5%	83.3%	0.417	0.875
occasionally	23.5%	16.7%		

Significant positive correlations were recorded between implant loss and the frequency of daily consumption of hard foods and hot beverages. Thus, participants who consumed hard foods or hot beverages daily lost more implants compared to those who consumed them occasionally (r=0.854 for hard foods and r=0.875 for hot beverages).

DISCUSSION

Systemic diseases including diabetes and osteoporosis are more common among older individuals seeking implant rehabilitation. The stability of osseointegration could be jeopardized if these illnesses negatively impact bone metabolism. Because we aimed on the dietary habits of the patients, we excluded from the study this type of patient, in order not to interfere with the results.

Dental implants can only last if the bone is healthy and the place is prepared correctly. Research has linked factors like cigarette use to clustering of dental implant failure patterns within participants. It is now well acknowledged that the bone should sustain minimum mechanical and thermal damage when the location is prepared for an implant. No research in Romanian literature has examined temperature variations in and around implants during normal oral functions, despite the fact that heat-induced bone injury may happen during uncontrolled drilling or acrylic polymerization near an implant abutment.

Exposure to heat, in terms of both tem-

perature and time, is the determinant of thermal damage. There has been reports of hyperemia at 40°C. At 42°C, proteins such procollagen and collagen I, which are essential in bone remodeling. Additionally, exposing cortical bone to 47°C for one-minute produces necrosis (20-23).

The oral cavity temperature can rise to 67°C16 and even 76°C to 77°C after drinking hot beverages, according to previous research (24, 25).Ex vivo simulations of implanted bovine mandibles showed that the highest temperatures recorded at the implant-bone interfaces were higher above the temperature threshold for transitory alterations in bone, which is 42°C (24). The importance of minimizing mechanical and thermal stress on the bone during the preparation of the implant site has recently been acknowledged.

A significant risk factor for late failure in the oral history is a history of periodontitis. A need for implant rehabilitation might be prompted by periodontitis, which is a leading cause of tooth loss. Not only that, but a prior review found that periodontitis is a risk factor for peri-implantitis, which in turn increases the likelihood of late failure (24). Inflammation around implants, known as peri-implantitis, is strongly linked to a patient's history of periodontitis, according to research by Jemt *et al.* (25). The transfer of periodontal bacteria from natural teeth to the implant may be the cause of this impact (26). Although peri-implantitis is an indication of late failure, only one study (11) looked at implant loss and not the correlation between a periodontitis diagnosis and late failure.

It is intriguing to note that according to two investigations, every individual who had a late loss had also suffered an early loss (25, 27). There was no statistical study done, however while treating patients who have experienced early implant loss, doctors should keep in mind that there is a substantial association between early and late implant loss.

While some studies have shown a link between posterior implant placement and late failure (17, 28, 29), others have failed to find such a correlation (30, 31). The reason behind the substantial association result could be because the occlusal forces on the back teeth are three times larger than on the front teeth (32). There is evidence that dental plaque accumulates more readily in posterior regions than in anterior ones, and that this buildup causes inflammation of the gums and the beginning of various oral disorders, all of which can contribute to the failure of dental implants (33).

The impact of maxilla implant site on late failure is debatable, despite the fact that it is known to increase the likelihood of early failure (34). Some research have suggested that implants put in the mandible (25, 35) or the maxilla (29) could increase the likelihood of late failure, while the majority of studies have shown that implant placement site does not significantly affect late failure (30, 31, 36).

Implant implantation in the maxilla may be associated with late failure because the cortical bone is thinner and the trabecular bone is less dense compared to the mandible (37, 38).

A decreased initial stability due to weakened bone structure increases the likelihood of dental implant failure in the long run (25). At the same time, it is not known why implants placed in the mandible are associated with late failure.

CONCLUSIONS

Osseointegration is the most important factor in the success of dental implant therapy. While dental implants are a reliable and popular option for individuals who are missing teeth, there is a risk that the high temperatures used to place the implants could harm the surrounding tissues and organs, leading to

unfavorable consequences. To sum up, we have tackled the intriguing issue of dental implants experiencing temperature variations and transitory heat transfer when hot liquids are consumed in this work.

According to our research, one possible cause of clustered implant failures is the regular drinking of very hot/cold drinks. It is possible to warn patients about the risk of harm from prolonged exposure to temperatures greater than 42°C or even 47°C at the interface between osseointegrated implants and bone, even if this risk has not been adequately studied.

Further clinical studies are required to determine whether the habitual consumption of hot food and beverages might be considered a risk factor in the success of implant-supported restorations.

It is recommended that additional research to be conducted in order to identify the possible risk of implant failure associated with the regular intake of extremely hot beverages, which patients rarely report.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NUTRITIONAL HEALTH IN ADULTS WITH DOWN SYNDROME LIVING IN URBAN NORTH-EASTERN ROMANIA **(**Abstract**):** Down syndrome is a genetic disorder typically linked with developmental delays, mild to moderate intellectual disability, and distinctive physical features. With a high prevalence of overweight and obesity, weight management strategies designed for the general population may not be suitable due to physiological and cognitive disparities in adults with DS. Weight issues in individuals with DS often stems from excessive calorie intake and inadequate physical activity, underscoring the importance of addressing dietary patterns. **Materials and methods:** We conducted a cross sectional study in the Cardiovascular Rehabilitation Clinic at Iasi Clinical Rehabilitation Hospital between July 1, 2022, and February 1, 2024. The study included 28 patients diagnosed with DS. We used SGA to assess nutritional status. **Results:** Among the patients, 25% were overweight and 39.3% were obese. Most obese individuals were from single-parent families (72.2%), performed minimal physical activity (81.81%), and exhibited poor dietary habits. In contrast, the overweight group had a more balanced diet, and superior hand grip strength, even outperforming the normal weight group. The obese group was the only one where we found scores of SGA over 9 points indicating an immediate need for nutritional intervention. **Conclusions**: Healthcare providers must address the unique challenges faced by adults with DS, including health conditions, feeding difficulties, and barriers to physical activity, while recognizing the critical role and stress experienced by caregivers. Despite the heightened risk of obesity, effective weight management is achievable with proper screening and intervention. **Keywords**: DOWN SYNDROME, NUTRITIONAL HEALTH, OBESITY.

Historically, weight gain was seen as a sign of health and prosperity. However, with industrialization and better living standards, obesity has become a major global health concern, affecting both children and adults (1). Obesity is now recognized as a leading cause of death, surpassing traditional health issues like infectious diseases (2). Despite advancements in diet, exercise, and treatments, obesity rates continue to rise, posing significant public health challenges (3).

The concept of genetic susceptibility to obesity was introduced in the early 20th century. Advances in genetics have since clarified specific forms of obesity linked to genetic defects (4).

BMI is commonly used to classify obesity in adults, defined by a value of 30 kg/m² or higher. However, BMI does not differentiate between muscle and adipose tissue. Waist circumference is often used as a practical measure of abdominal fat and related health risks (5, 6).

The International Association for the Scientific Study of Intellectual Disabilities (IASSIID) highlights the impact of obesity on individuals with intellectual disabilities, including Down Syndrome (DS) (7). DS is a genetic disorder characterized by intellectual disability and distinct physical traits, which currently has a life expectancy of around 60 years. (8, 9).

Recent studies show that adults with DS are at a higher risk of obesity due to factors like slower metabolism and low muscle tone, combined with challenges in maintaining healthy habits. Nutritional deficiencies and thyroid dysfunction are also more common in this group, requiring careful dietary management (10, 11). While general nutritional strategies apply, assessing nutritional status in adults with DS remains challenging due to limited research (12).

To our knowledge, this study represents the first comprehensive evaluation of the nutritional status within this particular population, addressing a significant gap in the literature, as no prior research has been conducted on the nutritional health of adults with Down syndrome in Romania.

MATERIALS AND METHODS

Study design

We conducted a descriptive cross-sectional study at the Cardiovascular Rehabilitation Clinic of the Iasi Clinical Rehabilitation Hospital between July 1st, 2022, and February 1st, 2024. The study cohort comprised 28 patients diagnosed with DS through genetic testing, selected from a total of 505 patients admitted to the clinic. Inclusion criteria for the study were: age over 18 years, a confirmed diagnosis of DS through genetic testing, and provision of informed consent. There were excluded: patients with recent surgical procedures, neoplasia, and those who were unable to complete the proposed assessments.

All participants were evaluated using a standardized clinical protocol by a single investigator. Demographic and clinical data included age, gender, body mass index (BMI), abdominal and calf circumference and handgrip strength. Additionally, data on family support, and whether the patient was from a single-parent household were gathered. The anamnesis also covered dietary habits, meal planning, and water intake.

The Subjective Global Assessment (SGA) is a widely validated tool for assessing malnutrition, combining clinical judgment with a detailed nutrition history and physical exam. It evaluates nine parameters: weight changes, food intake, gastrointestinal symptoms, functional capacity, comorbidities, subcutaneous fat, muscle loss, BMI, and serum albumin. Scores of 0-1 require reassessment, 2-3 suggest patient education, 4-8 call for dietary intervention, and scores over 9 need immediate nutritional intervention (13, 14).

Muscle strength was evaluated using an EH101 electronic dynamometer. Handgrip strength was measured with one familiarization trial and one test trial for both hands,

assessing maximal contraction over 4 seconds with verbal encouragement. We applied cut-off values from the European Working Group on Sarcopenia in Older People (EWGSOP): <30 kg for men and <20 kg for women.

Informed consent was obtained from all participants prior to their inclusion in the study. The study protocol received approval from the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi (208/9.07.2022) as well as the Iasi Clinical Rehabilitation Hospital (13/22. 06. 2023).

Data analysis

Statistical analysis was performed using SPSS version 20.0 (Statistical Package for the Social Sciences, Chicago, IL, USA). Variables that followed a normal distribution were reported as mean values with standard deviations and compared using the Student's t-test. For variables that did not follow a normal distribution, data were presented as medians with interquartile ranges and analyzed using the Mann-Whitney U test. Statistical significance was determined at a threshold of $p \leq 0.05$ for all analyses.

RESULTS

Our study included 28 patients, with a mean age of 28.07±9.51. All lived in urban area, were non-smokers and had family support.

As indicated in first table i, 25% of the patients were classified as overweight, and 39.3% as obese, predominately men. Within the obese group, 72.2% were from single-parent households and exhibited low physical activity levels (81.81%).

TABLE I.
General characteristics of the study group

	Normal Weight (n=10)	**Overweight** (n=7)	**Obese** (n=11)	p
Gender				
- Women	4 (40%)	3 (42.85%)	4 (36.36%)	0.96
- Men	6 (60%)	4 (57.15%)	7 (63.63%)	
Age	27.80±11.82	25.57±5.62	29.90±9.56	0.65
Environment				
- Urban	10 (100%)	7 (100%)	11 (100%)	-
- Rural	0 (0%)	0 (0%)	0 (0%)	
Smoker	0 (0%)	0 (0%)	0 (0%)	-
Physical activity				
- Minimal	5 (50%)	6 (85.71%)	9 (81.81%)	0.06
- Moderate	5 (50%)	1 (14.28%)	2 (18.19%)	
Family support	10 (100%)	7 (100%)	11 (100%)	-
Single parent family	5 (50%)	4 (57.15%)	8 (72.72%)	0.58

Obese adults with DS included in the study demonstrated poor dietary habits, including frequent fast food consumption (81.81%), low water intake (90.90% con-

suming only 500-1000 ml/day), and inadequate protein intake (only 36.36% regularly eating meat and 9.10% consuming fruits/vegetables more than twice a week or dairy daily). Hence, SGA scores above 9 points were found only in the obese group.

The mean BMI for the overweight group was towards the lower end of the range. In addition, they had the lowest mean SGA value (3.71 points) (tab. II).

TABLE II.
Physical and nutritional evaluation of the study group

	Normal Weight (n=10)	**Overweight** (n=7)	**Obese** (n=11)	p
Calf circumference (cm)	32.2±1.87	36.21±1.21	42.68±4.33	<0.00001
Abdominal circumference (cm)	85±9.93	91.57±6.79	114.77±12.47	<0.00001
Body Mass Index (kg/m^2)	23.17±1.93	26.77±1.14	38.69±8.52	<0.0001
Handgrip strength (kgf)				
- Dominant hand	14.70±2.89	15.21±4.14	13.90±2.76	0.68
- Nondominant hand	14.41±3.62	15.28±5.34	13.64±3.33	
SGA	4.5±2.01	3.71±1.60	5.90±3.44	0.21

In terms of lipid profile, we observed statistically significant differences in mean LDL cholesterol values. Although not statistically significant, it is worth mentioning that the obese group had the highest average of triglycerides, TSH levels and accentuated inflammatory status (tab. III).

DISCUSSION

Calories intake versus number of meals

The results in our study show that obese individuals have fewer meals per day compared to those who are overweight. One possible explanation is that meals, even few in number, are much higher in calories.

Our findings are consistent with those in the literature. In a Spanish cross-sectional study of 23 adults with DS, researchers used a consumption frequency questionnaire and the Mediterranean Diet Prevention Questionnaire to qualitatively assess dietary patterns. The study showed low intakes of vegetables, fruits, and dairy products, while the consumption of meat and sweet snacks were notably high (more than twice a week) (15).

Dratwa *et al.* (16) described in a study from 2023, the dietary habits of children and young adults with DS, pointing the importance of parental dietary mistakes. The study found that 62.6% of children had no nutritional restrictions, but some parents opted for a gluten-free (26.2%), lactose-free (28.7%), or no sugar diet (13.3%). The study concluded that while most children with DS have a balanced diet, parents often make nutritional errors.

Glucose levels

The results of the present study showed a mean glucose levels within normal ranges across the entire study group. Nevertheless, the mean glycemic index was notably lower in obese patients. Accordingly, a study conducted by Braunschweig *et al.* (17) in the United States (U.S.) while assessing the nutritional status of 48 adults with Down syndrome, revealed that 89% of participants were either overweight or obese, 54% had large waist circumferences, and none met the recommended guidelines for fruit and vegetable intake. Despite these findings, average glucose levels remained within normal ranges, and the prevalence of hypertension, elevated lipids, and glucose levels was lower compared to the general U.S. population.

Lipid profile

When analyzing the lipid profile, an intriguing paradox emerges: triglyceride levels exhibit the lowest mean values in overweight patients, while total cholesterol levels are highest among this group compared to the other patient categories. Overall, the only parameter that consistently

increases with weight is LDL cholesterol.

In an attempt to understand what leads to possible changes in the lipid variables of people with DS, some hypotheses were raised.

Excess weight and body fat, especially in the abdominal region, common among people with DS, may possibly interfere with lipid levels. Ordonez-Munoz *et al.* (18) found significant correlations between anthropometric variables (BMI, AC) and the lipid profile of young people with DS. However, Asua *et al.* (19) found that adult participants with abdominal obesity, did not present total cholesterol, LDLc, HDLc or triglyceride values different from those who were not identified with excess abdominal fat.

The understanding of thyroid function and its link to obesity in adults with DS is limited due to the scarcity of long-term follow-up data. As to the alterations in the lipid profile of the patients included in our study, hypothyroidism may also be related to changes in cholesterol, especially increased LDL. Studies and scientific papers have demonstrated that reduced thyroid hormone levels lead to decreased synthesis and expression of LDL receptors resulting in high serum levels of LDL and, consequently, increased cholesterol levels. (20).

Subjective Global Assessment

Findings in our study reveal that overweight patients had the best mean SGA score (3.71 points). Notably, 71% of these patients had scores ranging from 4 to a maximum of 8, indicating a clear need for dietary intervention. Conversely, the obese group showed a more urgent requirement for symptom management or nutritional intervention, with 54% of patients scoring between 4 and 8 and 20% achieving scores exceeding 9 points.

This discrepancy may be attributed to the fact that overweight individuals maintained a more balanced diet, with regular dairy and meat intake (70% and 80%, respectively), and a higher rate of adequate water consumption (60% drinking 1000 ml/day). This group also exhibited superior hand grip strength (15.21±4.14 and 15.28±5.34), even compared to the normal weight group, although only 14.28% engaged in moderate physical activity.

Recent literature indicates that SGA is a highly effective tool for nutritional diagnosis, often outperforming traditional methods such as anthropometry and laboratory data. However, its application in individuals with DS has not been extensively explored. This is a notable gap, considering the limited research on nutrition for individuals with DS, where many studies depend on less precise nutritional questionnaires and caregiver assessments (13, 21, 22).

Water intake

Previous research has consistently highlighted a concerning trend of dehydration among individuals with DS (23, 24). This issue is often linked to anatomical changes or muscle hypotonia. Additionally, studies have shown a troubling preference for sweet beverages over plain water in this population (15, 16). This underscores the vital role that family members and caregivers play in steering adults with DS toward healthier dietary and hydration habits.

Our study's findings resonate strongly with these observations, revealing not only insufficient water intake across all patient groups but also a worrying tendency toward fast food consumption, particularly among those with obesity. Most alarmingly, our results indicate a predominant association with a mean renal function gradient (RFG) suggestive of renal distress. One

possible explanation for this issue may be closely tied to the high intake of animal and vegetable protein (70%), further emphasizing the need for targeted interventions to improve dietary habits and prevent serious health complications in this vulnerable population.

Weight management strategies for individuals with DS include portion control, increased fiber and vegetables, and regular physical activity tailored to their abilities. The "GLOBAL Medical Care Guidelines for Adults with DS" provide recommendations, but more research is needed on the combined effects of diet, exercise, and calorie management in this population (25).

Limitations of the study

The limitations of our study include the small sample size and the lack of a control group without Down syndrome DS. These factors may limit the ability to generalize the findings and might impact the strength of the conclusions. They also present challenges in relating variables to accurately represent the broader DS population. Furthermore, the relatively small number of studies on adults with DS, compared to those focused on pediatric populations, underscores the need for additional research targeting this specific group.

CONCLUSSIONS

This study highlights that while overweight status can be relatively manageable for a patient with DS, progression to obesity presents significant health risks and can lead to rapid deterioration in health outcomes. The data emphasize the urgent need for early intervention upon the onset of obesity. It is imperative that families receive targeted education regarding nutritional guidelines and management strategies specifically designed for individuals with DS, due to their distinct obesity-related challenges.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

EPIDEMIOLOGY AND DEMOGRAPHIC PATTERNS OF RADIAL HEAD FRACTURES: A TWELVE-YEAR ANALYSIS FROM A TERTIARY TRAUMA CENTER (Abstract): Radial head fractures represent approximately 33% of all elbow fractures, displaying a bimodal incidence pattern predominantly affecting younger males through high-energy impacts and older females due to low-energy trauma. Classified by the Mason system, these fractures range from minor displacements to complex, comminuted fractures that often require surgical management. **Materials and methods:** This retrospective and prospective study included 311 patients with radial head fractures admitted between 2011 and 2023 to the Department of Orthopedics-Traumatology at "Sf. Spiridon" County Clinical Emergency Hospital Iasi We collected data encompassed demographic information, fracture classification, associated injuries and aimed to identify demographic patterns and risk factors associated with radial head fractures. Statistical analyses were conducted using *SPSS version 18.0*. **Results:** The study confirmed a bimodal distribution in fracture incidence, with Mason III and Mason IV types being most common. Gender analysis showed that males were four times more likely to have the terrible triad fracture pattern compared to females (OR = 4.00; 95% CI: 1.09-14.6; p = 0.025). Age-related analysis indicated that olecranon-associated fractures were 1.69 times more common in patients aged 45 and above (OR = 1.69; 95% CI: 1.36-2.10; p = 0.001), whereas younger patients were more prone to the terrible triad, though statistical significance was marginal (p = 0.085). **Conclusions:** Radial head fractures exhibit distinct demographic patterns, with age and gender influencing fracture type distribution. These insights underline the importance of targeted diagnostic and management strategies, particularly for high-risk fracture patterns, to improve patient outcomes in radial head fractures. **Keywords:** RADIAL HEAD FRACTURE, MASON CLASSIFICATION, EPIDEMIOLOGY, AGE AND GENDER DISTRIBUTION, RISK FACTORS.

INTRODUCTION

The radial head is essential for elbow joint biomechanics, particularly in stabilizing the elbow through the radio-capitellar joint. Is the primary structure providing longitudinal stability for the forearm. Roughly 60% of the mechanical load on the elbow is absorbed through the radial column

(1, 2).

Radial head fractures account for 17-19% of elbow trauma cases and constitute 33% of elbow fractures (1) and approximately 1.7% to 5.4% of all fractures (3), with an estimated annual incidence rate of 25 to 55.4/100,000 people. This rate has been increasing, likely due to an aging population and a widespread participation in high-risk activities (4, 5). Epidemiologically, radial head fractures display a bimodal distribution: younger males are more prone to high-energy impacts, such as sports injuries or falls from height, resulting in complex fractures, (6) while older females often sustain simple fractures from low-energy mechanism, potentially due to osteoporosis (7, 8). The peak incidence is around 37 years for men and 52 years for women (9).

The Mason classification, initially introduced in 1954 (10) and modified by Johnston in 1962 (11), is widely used for evaluating radial head fractures, guiding both preoperative planning and prognostic assessment. The system categorizes fractures from Type I (non-displaced) to Type IV (displaced with dislocation), with treatment ranging from non-operative approaches to open reduction and internal fixation (ORIF) or radial head arthroplasty (RHA) for more complex injuries. Recently, RHA has gained popularity for complex fractures due to its stability benefits, particularly in cases where excision or non-operative treatment may not provide adequate joint support (12). This shift underscores the importance of individualized treatment, considering factors like age, trauma mechanism, and fracture complexity to optimize outcomes.

MATERIALS AND METHODS

The study included 311 adult patients diagnosed with radial head fractures, admitted between 2011 and 2023 to the Department of Orthopedics-Traumatology at "Sf. Spiridon" County Clinical Emergency Hospital from Iasi. Data were gathered both prospectively and retrospectively from our computerized patient records database, containing variables such as age, gender, socio-economic status, injury mechanism, method of treatment, period of hospitalization and immobilization after surgery, comorbidities and associated injuries.

Radial head fractures were categorized using the Mason classification. Statistical analysis was conducted using *SPSS version 18.0,* employing both parametric and non-parametric tests. The choice of statistical test depended on the nature of the data: t-tests and F-tests (ANOVA) were applied for comparing quantitative variables, while chi-square tests were used for categorical data to evaluate frequency distributions. We maintained a 95% confidence interval (CI) for all tests to ensure reliable statistical significance, with chi-square tests applied to assess differences in fracture distribution by age and gender.

To examine fracture incidence trends over time, linear regression analyses were conducted on the annual hospital admissions. The coefficient of variation (CV%) was calculated to assess homogeneity within data sets, and the Skewness test was applied to validate the normality of the data for continuous variables.

RESULTS

Over the 12-year study period, annual hospital admissions showed a decreasing trend ($y = 2727 – 47x$), projecting approximately 2,116 admissions for 2024. However, the distribution of radial head fracture cases initially increased, peaking in 2018 at 9.4% of admissions, before declining in recent years ($y = 9.68 - 0.34x$). Projections

estimate a 5% frequency in 2024 (tab. I). The distribution of cases was bimodal, with 12.2% in 2015 and 12.9% in 2022, showing an upward trend (y = 4.92 + 0.40x), predicting an incidence of approximately 10.5% in 2024 (fig. 1). Throughout the months of the study, an increased frequency of cases was observed in May (11.6%), July (11.3%), and September (11.3%). The monthly percentage distribution during the analyzed period showed no significant differences (y = 7.99 + 0.06x; p = 0.094).

TABLE I.

Annual admissions and case distribution of radial head on year study

Year study	Admissions	% from total	Cases of radial head fracture	Cases / 1,000 admissions
2011	1771	5.7	7	3.95
2012	2762	8.8	14	5.07
2013	2750	8.8	20	7.27
2014	2769	8.9	24	8.67
2015	2813	9.0	38	13.51
2016	2362	7.6	35	14.82
2017	2874	9.2	14	4.87
2018	2934	9.4	21	7.16
2019	2816	9.0	31	11.01
2020	1400	4.5	14	10.00
2021	1630	5.2	22	13.50
2022	2022	6.5	40	19.78
2023	2313	7.4	31	13.40
Total	31216	100.0	311	9.96

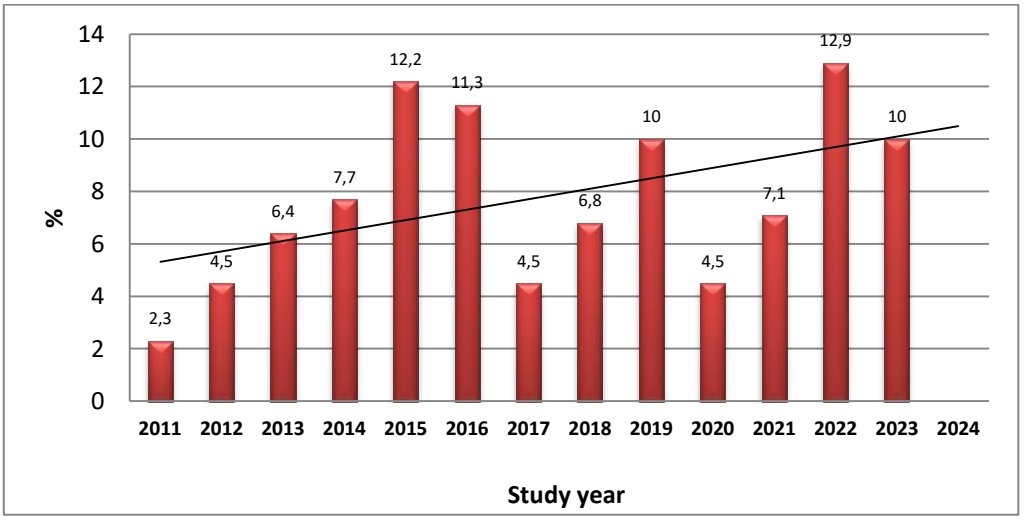

Fig. 1. Case distribution by year of study

The study population ranged from 18 to 94 years, with a mean age of 46.56 ± 15.86 years, close to the median age (45 years), with the Skewness test result (s = 0.266) suggesting homogeneity in the data series, allowing for the application of statistical significance tests. Gender distribution showed no significant differences, with 49.2% men and 50.8% women. The mean age was significantly higher in females (38.56 *vs.* 54.31 years; p = 0.001). In the age group under 45 years, male cases predominated (71.2%), while in the age group over 45 years, female cases were more prevalent (72.8%) (p = 0.001) (fig. 2).

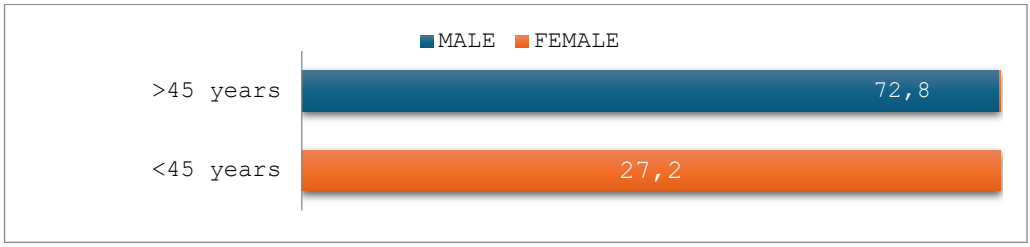

Fig. 2. Case distribution based on gender and age group

Among study participants, 23.2% of patients were unemployed, while over half were employed (50.2%). Educational status was low for 45% of the study group, though most patients had completed high school (43.7%) (fig. 3).

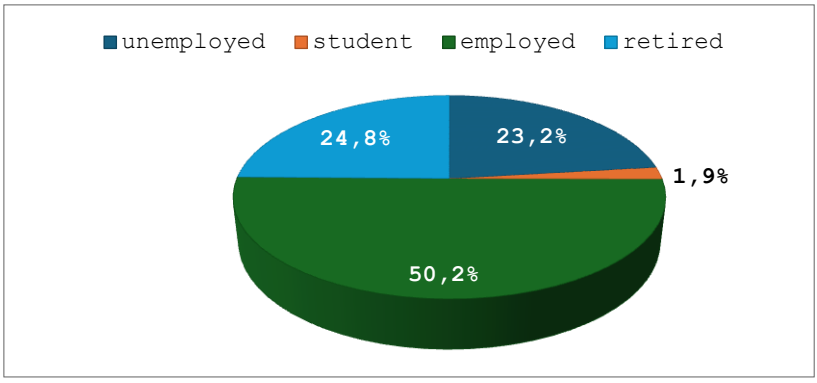

Fig. 3. Distribution of patients by educational status

The findings related to weight status in the study group show a total of 48.6% of cases were overweight, and 15.4% had grade I obesity. Obesity was observed in 14.5% of men and 29.8% of women (p = 0.008) (tab. II).

The left limb was more frequently affected (53.4%). Among patients with the left limb affected, 52.2% were male (p = 0.272), and 52.4% were over 45 years of age (p = 0.633). For patients with the right limb affected, 55.4% were female (p = 0.274), and 50.4% were over 45 years of age (p = 0.637). Among patients with both limbs affected, 86.7% were male (p = 0.272), and 66.7% were under 45 years of age (p = 0.633).

TABLE II.
Weight status by gender

Weight status	Male (n=153)		Female (n=158)	
	n	%	n	%
Normal weight	43	28.1	48	30.4
Overweight	88	57.5	63	39.9
Obesity Ist degree	16	10.5	32	20.3
Obesity IInd degree	5	3.3	12	7.6
Obesity IIIrd degree	1	0.7	3	1.9

The most common associated fractures were of the olecranon (8.7%), followed by the coronoid process (7.7%) and distal radius (4.8%) or Monteggia-like lesion (4.8%). The estimated risk (RR), by gender (tab. III), of an associated olecranon fracture was 1.52 times higher in females (RR = 1.52; 95% CI: 1.18-1.96; p = 0.01) and of an associated coronoid process fracture was 1.30 times higher in males (RR = 1.30; 95% CI: 0.93-1.81; p = 0.173). The risk of an associated Monteggia-type dislocation was 1.19 times higher in females (RR = 1.19; 95% CI: 0.78-1.83; p = 0.464).

TABLE III.
Estimated risk of associated fractures by gender

Associated fractures	Male (n=153)		Female (n=158)		p	RR	95% CI
	n	%	n	%			
Olecranon	7	4.6	20	12.7	**0.010**	1.52$_F$	1.18-1.96
Coronoid process	15	9.8	9	5.7	0.173	1.30$_M$	0.93-1.81
Distal radius	8	5.2	7	4.4	0.742	1.09$_M$	0.67-1.77
Monteggia-like lesion	6	3.9	9	5.7	0.464	1.19$_F$	0.78-1.83

By age group (tab. IV), the risk of an associated olecranon fracture was estimated to be 1.69 times higher in the age group over 45 years (RR = 1.69; 95% CI: 1.36-2.10; p = 0.001) and of an associated coronoid process fracture was estimated to be 1.31 times higher in the age group under 45 years (RR = 1.31; 95% CI: 0.94-1.83; p = 0.163). The risk of an associated Monteggia-like lesion was estimated to be 1.76 times higher in the age group over 45 years (RR = 1.76; 95% CI: 1.40-2.21; p = 0.003). In the gender-based distribution (tab. V). fractures were categorized by the Mason classification types I to IV. Essex-Lopresti fracture-dislocation (radial head fracture, rupture of the forearm interosseous membrane and distal radio-ulnar joint dislocation), and the terrible triad (radial head fracture, coronoid process fracture and elbow dislocation). Among males (n=153) and females (n=158), the most common fracture types were Mason III and Mason IV. The chi-square test showed no statistically significant gender

difference for most fracture types, except for the terrible triad, which was more common in males (7.2%) compared to females (1.9%) with a significant p-value of 0.025.

The odds ratio indicated that males had a fourfold higher likelihood of experiencing terrible triad fractures (OR = 4.00, 95% CI: 1.09-14.6).

TABLE. IV

Estimated risk of associated fractures by age

Associated fractures	≥ 45 years (n=159)		< 45 years (n=152)		p	RR	95% CI
	n	%	n	%			
Olecranon	22	13.8	5	3.3	**0.001**	1.69 $_{45+}$	1.36-2.10
Coronoid process	9	5.7	15	9.9	0.163	1.31 $_{<45}$	0.94-1.83
Distal radius	8	5.0	7	4.6	0.861	1.05 $_{45+}$	0.64-1.70
Monteggia-like lesion	13	8.2	2	1.3	**0.003**	1.76 $_{45+}$	1.40-2.21

TABLE V.

Distribution of cases by gender correlated with fracture type

Fracture type	Male (n=153)		Female (n=158)		Chi^2 test p	OR	95% CI
	n	%	n	%

For age-based distribution (tab. VI), patients were split into two groups: those aged ≥45 years (n=159) and those under 45 years (n=152). The analysis indicated that Mason III and Mason IV fractures were the most prevalent across both age groups, showing no significant differences by age. However, Essex-Lopresti fracture-dislocation were more frequent in patients under 45 years (2.0%) compared to older patients (0.6%), though this finding was not statistically significant (p=0.294). The terrible triad was more common in patients younger than 45 (6.6%) compared to those 45 and older (2.5%), with an OR of 2.73, though the p-value was 0.085, indicating a trend but not statistical significance.

TABLE VI.
Distribution of cases by group age correlated with fracture type

Fracture type	≥ 45 years (n=159)		< 45 years (n=152)		Chi² test p	OR	95% CI

DISCUSSION

This study provides valuable insights into the epidemiological and demographic patterns associated with radial head fractures. Consistent with prior research (13), we found a bimodal age and gender distribution, where younger males frequently sustained high-energy injuries resulting in complex fractures, while older females were more likely to experience low-energy fractures, possibly due to osteoporosis and other age-related factors.

The increased prevalence of Mason III and IV fractures aligns with previous studies, which also identified these types as common in radial head fractures requiring surgical intervention. Associated injuries with radial head fractures are increasingly recognized for their clinical significance (14, 15). Our findings regarding the terrible triad pattern are particularly noteworthy. Consistent with the literature, this study revealed that younger males had a significantly higher likelihood of experiencing terrible triad fractures (OR = 4.00, p = 0.025), a finding that underscores the impact of high-energy trauma in this demographic. The higher rate of olecranon fractures in older females similarly echoes findings from other epidemiological studies, suggesting a heightened vulnerability to specific fracture patterns in this group due to bone density loss.

Our analysis also highlighted the distinct risk factors associated with gender and age. The increased risk of olecranon and Monteggia-like fractures in patients over 45 years reinforces the need for targeted diagnostic approaches in elderly patients, especially females. These age- and gender-specific findings suggest that healthcare providers should consider demographic factors when assessing and planning treatment for radial head fractures.

The demographic insights gained in this study have implications for clinical practice, particularly in the development of tailored treatment protocols. For example, males under 45 with high-energy injuries may benefit from more intensive imaging

to identify the potential for complex fracture patterns like the terrible triad. For females over 45, early intervention strategies focusing on osteoporosis management could reduce the likelihood of low-energy fractures and improve patient outcomes.

While this study presents robust data from a large sample over 12 years, some limitations must be acknowledged. The single-center design may limit the generalizability of our findings to other regions or populations. Additionally, although the study includes comprehensive demographic and clinical data, factors such as lifestyle and physical activity levels, which may influence fracture risk, were not assessed. Future studies that incorporate these variables could provide a more holistic view of fracture risk factors.

Also, future research should focus on longitudinal studies correlating fracture types and surgical procedures with clinical outcomes. Evaluating the effectiveness of interventions like radial head arthroplasty across various fracture types and patient demographics would provide valuable data to refine treatment protocols.

Additionally, exploring the relationship between bone health interventions and fracture incidence in older patients, especially postmenopausal women, may help establish preventative strategies.

CONCLUSIONS

In conclusion, this 12-year study on radial head fractures highlights distinct demographic patterns, with younger males more prone to high-energy fractures and older females to low-energy fractures. The findings confirm that Mason III and IV fractures are the most prevalent and often require surgical intervention. Gender and age disparities, such as the higher incidence of the terrible triad in males and olecranon-associated fractures in females, underscore the importance of individualized diagnostic and treatment approaches tailored to patient demographics.

This study's large sample size provides valuable insights into the epidemiology and demographics of radial head fractures, emphasizing that targeted management strategies can enhance patient outcomes. Further research into the relationship between fracture types, clinical outcomes, and specific treatment approaches may help refine guidelines and improve patient care.

ACKNOWLEDGEMENTS

Studies such as these would be impossible without the constant support from the whole staff, residency and clinical leads that always advocate for further development of education and training.

NON-TRAUMATIC NON-COVID-19 RELATED FINDINGS IN EMERGENCY CHEST MULTIDETECTOR COMPUTED TOMOGRAPHY: A RETROSPECTIVE STUDY (Abstract): This study **aims** to analyze the non-traumatic and non-COVID-19-related findings detected in patients presenting to the emergency department with acute chest pain who underwent chest multidetector computed tomography (MDCT) and the relationship with patient gender and treatment solutions. **Materials and methods:** We retrospectively selected and reviewed the radiological reports of a cohort of 378 patients who underwent chest MDCT in emergency at "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, Romania, between January 1, 2021, and July 1, 2024. Exclusion criteria were recent trauma history, a positive PCR test for COVID-19, and acute myocardial infarction. MDCT examinations were performed using a 16-slice Siemens Somatom Emotion CT scanner and a 64-slice Philips Incisive CT scanner. **Results:** Among the 378 patients, 222 were males (58.7%) and 156 were females (41.3%), with a mean age of 73.8 years (SD 10.767; CI 72.55-75.06; range 35-94 years). We classified the lesions into four categories: pleuro-pulmonary (51.58%), cardiac (24.9%), vascular (16.55%), malignant (6.97%). Life-threatening findings were present in only 21.42% of cases, including pulmonary embolism (14.8%), acute pulmonary edema (2.3%), descending aorta dissection (0.7%), and massive pleural effusion (0.7%). The most common primary malignancy was lung cancer. **Conclusions**: This study underlines the importance of correctly identifying and managing the chest CT findings in the case of patients examined in emergencies. **Keywords:** CHEST EMERGENCY, COMPUTED TOMOGRAPHY, NON-TRAUMATIC, NON-COVID-19, ACUTE CHEST PAIN.

INTRODUCTION

Chest multidetector computed tomography (MDCT) became an essential tool in emergency departments due to its ability to provide fast, accurate, high-resolution diagnostic images and to evaluate the cause and extent of the disease (1, 2, 3, 4).

Chest pain and shortness of breath are determined only in a small percentage by acute coronary syndrome, even if ischemic heart disease is frequent and often clinically indistinguishable from other chest conditions (5-10); the differential diagnosis includes gastro-esophageal diseases, chest-wall syn-dromes,

and less frequent causes: pulmonary embolism, pleural and pericardial lesions, pneumonia, lung cancer, aortic dissection, and herpes zoster. Among them, there are several life-threatening causes: pulmonary embolism (PE), tension pneumothorax, pericardial tamponade, aortic dissection, and esophageal perforation, which can be confidently and rapidly diagnosed by chest CT (8, 9, 10). PE is the third most common cause of cardiovascular-related deaths, following myocardial ischemia and stroke (11-13), and for its diagnosis, the gold-standard investigation is computed tomography pulmonary angiography (CTPA) (13, 14), with a high sensitivity (96-100%) and specificity (97-98%) (14, 15).

Previous studies have established the efficacy of MDCT in evaluating thoracic emergencies (7, 8, 16, 17); however, regional data, particularly from Eastern Europe, remain limited (18, 19).

MATERIALS AND METHODS

We retrospectively searched and randomly selected from the hospital databases 378 patients who presented to the emergency department (ED) at "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, Romania, between January 1, 2021, and August 31, 2024, with acute chest pain and undergone a chest MDCT. We reviewed all the reports and DICOM images of 191 non-enhanced chest CT (for evaluating lung lesions described on chest x rays) and 187 contrast-enhanced chest CT (to rule out mainly pulmonary embolism or a thoracic aortic dissection). The exclusion criteria from the study were: a recent traumatic history, a positive PCR test for COVID-19 or an acute myocardial infarction.

CT examinations were performed on a 16-slice Siemens Somatom Emotion CT scanner and a 64-slice Philips Incisive CT scanner using standard protocol settings. A non-contrast CT chest protocol was conducted on all patients. To rule out a life-threatening cause of acute chest pain, such as a pulmonary embolism or aortic dissection, the non-enhanced scan was followed by a contrast-enhanced CT with the administration of non-ionic iodinated contrast material (Iopromidum, Ultravist 370, 370 mg/mL, Bayer, Leverkusen, Germany).

Statistical analyses were conducted using *SPSS software for Mac version 29.0* (SPSS, Chicago, IL, USA). Continuous variables are provided as the mean ± standard deviation (SD), while nominal variables are shown as frequencies and percentages. There were six main categories for nominal variables: pleural and pulmonary findings, (non-coronary) cardiac findings, vascular findings, urgent findings, malignant findings, and other findings. To identify significant parameters in our population study, we used Pearson's chi-squared test (non-parametric analysis) for categorical variables. A p-value less than or equal to 0.05 was considered statistically significant.

RESULTS

Among the 378 patients, 222 were males (58.7%), and 156 females (41.3%), with a mean age of 73.8 years (SD 10.767, CI 72.55-75.06; range 35-94 years), and we discovered only 81 cases (21.42%) that needed immediate treatment (emergencies). We classified the non-emergency findings into four categories: pleuro-pulmonary lesions (51.48%) heart diseases (24.9%), vascular conditions (16.55%), malignant findings (6.97%). Most of the patients had several lesions present, and the most common findings were pleural effusion (n=156, 41.2%), valvular calcifications (n=84, 22.2%), cardiomegaly (n=73, 19.3%), pulmonary embolism (n=56, 14.8%).

Emergency findings. The most important discoveries were the emergency diagnostics, representing 21.42% (n=81),

the most frequent of all being pulmonary embolism, found on 14.8% of patients, followed by acute pulmonary edema (2.3%, n = 9), descending aorta dissection (0.7%, n = 3), and massive pleural effusion (0.7%, n = 3). These patients have been referred to specialists for immediate treatment.

In our study the localization of emboli was as following: in main pulmonary arteries (4.4%, n = 17), lobar (3.9%, n = 15), and segmental arteries (5%, n = 19), but the filling defects in subsegmental arteries are difficult to depict, probably that's why we detected them only in 5 cases (1.3%); nevertheless, subsegmental pulmonary embolism is not considered to be significant for the diagnosis (18,19). Pulmonary infarction was present in 2.1 cases (8%).

There was no significant gender association in either pulmonary embolism or pleural effusion, both having approximately equal distribution in both genders.

Pulmonary embolism was strongly correlated with pulmonary hypertension (dilated pulmonary trunk > 33 mm) ($p < 0.001$).

Pleural effusion often accompanies pulmonary embolism, due to the hemodynamic changes and increased pressure in the pulmonary circulation caused by emboli ($p<0.05$)

Patients presenting with acute pulmonary edema often had cardiomegaly, due to underlying heart conditions contributing to fluid accumulation in the lungs ($p<0.05$).

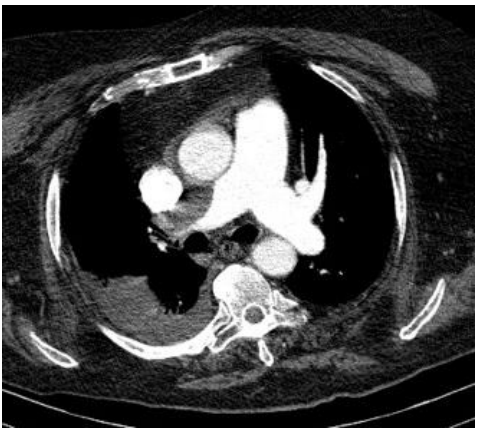

Fig. 1. CTPA-thrombus in the right pulmonary artery, enlarged main pulmonary artery, right pleural effusion, and adjacent lung collapse**.**

Descending aorta dissection was significantly correlated with hypertension ($p < 0.001$). There was a correlation between massive pleural effusion and underlying malignancies, such as bronchopulmonary cancer ($p= 0.04$).

Examining CT images, we depicted on the abdominal sections, beside chest emergencies, also some abdominal lesion worth mentioning (tab. I); for these diagnostics also an immediate treatment was done. These insights can be valuable for understanding the complexity of patient conditions and planning appropriate diagnostic and treatment strategies.

TABLE I.

Summary of emergency diagnostics

Emergencies	No. of patients=81	21.42%
Acute pulmonary embolism	56	14.81
Acute pulmonary edema	9	2.38
Descending aorta dissection	3	0.79
Mesenteric ischemia	3	0.79
Massive pleural effusion	3	0.79
Tension pneumothorax	3	0.79
Small bowel obstruction	2	0.52
Acute pancreatitis	2	0.52

Pleuro-pulmonary findings (tab. II) were found in 195 patients (51.58%) with multiple findings for each patient; the most common are the following: pleural effusion (41.2 %, n = 156), fibrotic bands (33 %, n = 125), non-calcified pulmonary nodules (18.2 %, n = 69), pulmonary emphysema (17.9 %, n = 68), and pulmonary tuberculosis sequelae (12.4 %, n = 47).

Pleural effusion (causing pleuritic chest pain, dyspnea, and a dry cough) (20) was the most common finding in our study (41.2%, n = 156), but only in three cases (0.7%) with massive pleural effusion an immediate treatment was necessary. The study found no significant correlation with gender (p=0.52), but there was a significant association between pleural effusion and pulmonary hypertension (pulmonary trunk > 33 mm), pericardial effusion, and cardiomegaly ($p < 0.001$).

Pulmonary emphysema is one of the most frequent lung conditions (21), depicted in our study in 68 cases (17.9%). Males are more likely to be affected ($p < 0.001$). Patients with pulmonary emphysema have also fibrotic bands ($p < 0.01$).

Non-calcified pulmonary nodules were found in 69 patients (18.2%). According to updated Fleischner Society Guidelines for managing incidental non-calcified pulmonary nodules; were divided by structure in two groups (solid and subsolid) and by dimension in three groups (< 6 mm, 6-8 mm and > 8 mm).

TABLE II.

Summary of pleuro-pulmonary findings

Pleuro-pulmonary findings	No. of findings	Frequency (%)
Pleural effusion	156	41.26
Fibrotic bands	125	33
Non-calcified pulmonary nodule	69	18.2
Pulmonary emphysema	68	17.9
Pleural and pulmonary tuberculosis sequelae	140	36.9
Bronchiectasis	34	8.9
Pneumonia and Bronchopneumonia	28	7.2
tuberculosis	4	1
Lung cancer	9	2.3
Pulmonary infarct	8	2.1
Pulmonary metastases	4	1

A single solid nodule < 6 mm was found in 8 patients (2.1%), with no CT follow-up recommended. A single solid nodule > 8 mm was found in 3 patients (0.7 %), with recommendation for chest CT follow-up after 3 months.

Multiple solid nodules < 6 mm were found in 15 patients (3.9%) (no follow-up was recommended) and with diameters of 6-8 mm in 37 patients (9.7 %) with a recommendation for a further chest CT after 6 months.

Calcified nodules were considered sequelae of tuberculosis, and they don't need follow-up. There was a male predominance associated with calcified pulmonary nodules ($p < 0.01$).

The correlation matrix of diagnosis reveals significant relationships between various diagnoses (fig. 2), highlighting the interconnected nature of pleuro-pulmonary, cardiac, vascular, and malignant conditions.

The study found that: pulmonary emphysema was highly correlated with cardiomegaly (0.96) and valvular calcification (0.88); lung cancer was moderately correlated with pulmonary emphysema (0.33); cardiomegaly was highly correlated with pulmonary emphysema (0.96) and valvular calcifications (0.80), moderately correlated with fibrosis (0.70) and pericardial effusion (0.58); pericardial effusion was highly correlated with dilated pulmonary trunk(0.89), moderately correlated with valvular calcification(0.64) and cardiomegaly (0.58); dilated pulmonary trunk was highly correlated with pericardial effusion 0.89), moderately correlated with pulmonary emphysema (0.74), dilated pulmonary trunk is highly correlated with pericardial effusion (0.89).

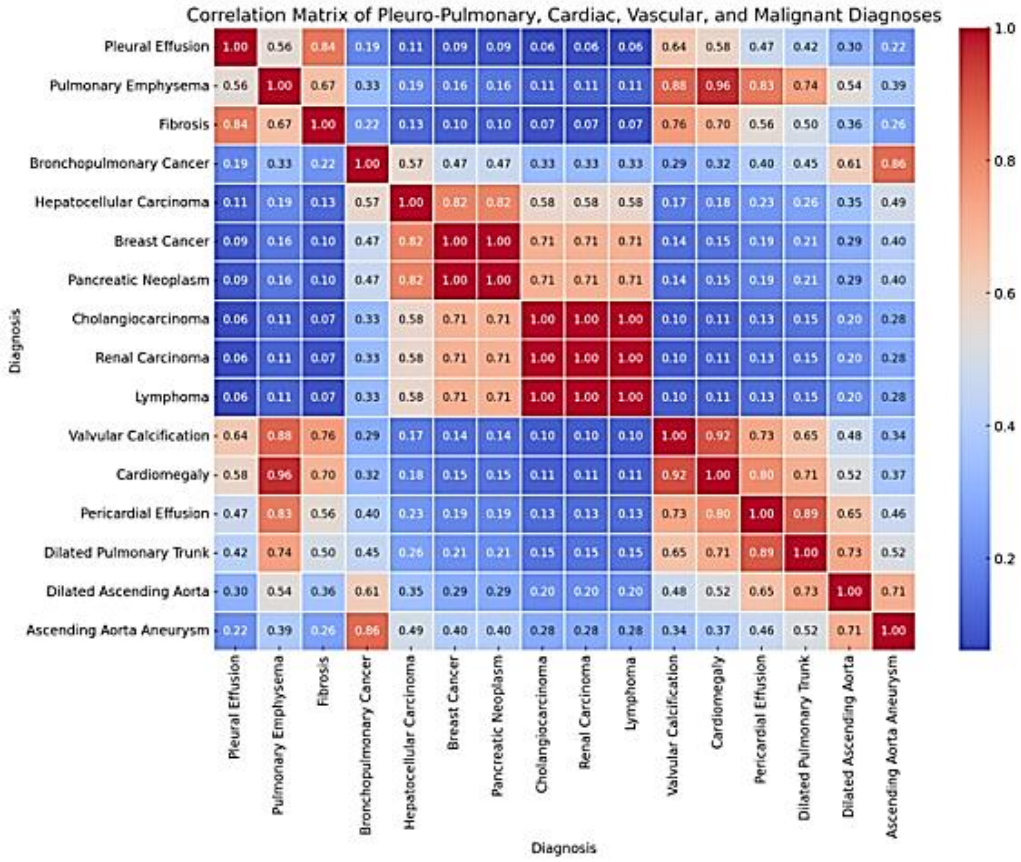

Fig. 2. Correlation matrix revealing significant relationships between various diagnoses

Heart diseases. We found heart diseases in 24.9% patients: valvular calcification (22.2%, n = 84 divided between aortic valve calcification 14.5%, n=55 and mitral valve calcification 7.6%, n = 29), cardiomegaly (19.3%, n=73), pericardial effusion (13.2%, n = 5), pericardial cyst (0.2%, n=1). 21 patients had cardiomegaly and pericardial effusion all together. Cardiomegaly was associated with female gender ($p < 0.05$).

Vascular findings (tab. III) were found in 16.55% of patients. In descending order, we found the fallowing: dilated pulmonary trunk > 33 mm (10.8 %, n=41), dilated ascending aorta > 40 mm (6 %, n=23), descending aorta dissection (0.7%, n=3), ascending aorta aneurism (3.1 %, n=12).

According to studies, main pulmonary artery has normally less than 33 mm. Above this level (with a sensitivity of 58% and a specificity of 95%), pulmonary arterial hypertension should be suspected. There was a significant association between pulmonary hypertension and acute pulmonary embolism, between pulmonary hypertension and pericardial effusion, and between pulmonary hypertension and cardiomegaly ($p < 0.05$).

TABLE III.
Summary of vascular findings

Vascular findings	No. of findings	%
Pulmonary trunk > 33 mm	41	10.8
Dilatation of the ascending aorta (40-50 mm)	23	6.0
Significant Superior mesenteric artery stenosis > 50 %	18	4.7
Ascending aorta aneurism (> 50 mm)	12	3.1
Significant Celiac trunk stenosis >50 %	7	1.8
Descending aorta dissection	3	0.7

Malignant lesions. Among chest malignant lesions (n=19, 6.97%), the most frequent primary tumor in both genders was lung cancer (2.3%, n = 9), followed by breast cancer (1.2%, n=2). Important incidental findings were depicted at the abdominal level and were reported within the limits of the performed protocol. Therefore, we discovered hepatocellular carcinoma (0.79%, n = 3), pancreatic cancer (0.53%, n = 2), cholangiocarcinoma, renal carcinoma, lymphoma (0.2%, n = 1 each). We depicted also secondary lesions with several localizations: liver (1.8%, n = 7), bones (1.5%, n = 6), lungs (1%, n = 4), adrenal glands (1%, n = 4), peritoneum (0.3%, n = 1). Patients with these incidental malignant findings were referred for an oncology consultation to establish disease management (20, 21, 22).

DISCUSSION

This retrospective study on non-traumatic, non-COVID-19-related CT findings in case of patients presenting with acute chest pain demonstrates the critical role of MDCT in diagnosing a wide array of conditions, differentiating the emergencies from non-emergency cases, and establishing an appropriate case management (23, 24).

The mean age in population study was 73.8 years, indicating a significant proportion of old patients. This demographic is particularly relevant because older individuals are more likely to present with multiple comorbidities and complex medical conditions, which can complicate the diagnosis and management of acute chest pain.

This study reveals that pleuropulmonary and vascular findings are prevalent, with pleural effusion and pulmonary embolism being particularly frequent.

Thoracic emergencies were found on only 21.4% of patients. The most frequent one was pulmonary embolism. There were no significant gender differences for most

conditions except pulmonary emphysema, which was more common in males ($p < 0.001$), and cardiomegaly, which was associated with females ($p < 0.05$).

Malignant tumors (25, 26) and cardiovascular disorders (27) were incidental findings which were depicted frequent enough among our patients and were referred for treatment in dedicated departments.

CONCLUSIONS

Given that we encountered mainly elder patients, our findings emphasize the importance of an accurate diagnostic and therapeutic approach in cases presented with chest acute pain in order to ensure rapid and correct identification of a potentially life-threatening condition.

This study is conducted on a limited number of patients, but it can fill a gap in the Romanian healthcare context by providing useful data about the diagnosis depicted by chest CT for patients with acute chest pain, which can be useful for local practitioners.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

RP-HPLC METHOD WITH UV DETECTION FOR THE EVALUATION OF CHITOSAN-GRAFT-B-CYCLODEXTRIN/PVA HYDROGELS AS CARRIERS FOR THE CONTROLLED RELEASE OF VEMURAFENIB (Abstract): When developing a topical formulation, it is essential to evaluate it from the perspective of its carrier capacity for the controlled release of the encapsulated drug. The drug should be simply quantified through an accurate and reproducible method. This paper presents a rapid, simple, sensitive, and reproducible high-performance liquid chromatography method with UV detection for evaluating the ability of chitosan-graft-β-cyclodextrin/PVA (CS-g-β-CD/PVA) hydrogels as carriers for the controlled release of vemurafenib (VEM). **Materials and methods:** The chromatographic separation was achieved using a Waters CORTECS C18 column (100 × 2.1 mm ID, 2.7 µm). The mobile phase was a mixture of: A (water/formic acid - 99.9/0.1, v/v), B (acetonitrile), and C (methanol) in the ratio of 40: 55: 5 (v/v/v). The injection sample amount was 10 µL, and the run time was 9 minutes in isocratic mode at a flow rate of 1 mL/min. The analyte was detected using UV absorption at 252 nm. **Results:** The standard calibration curve was linear over the concentration range of 0.78-100 mg/L. The values for LOD and LOQ were 0.5 mg/L and 0.75 mg/L, respectively. The intra- and inter-day precision of measurements were lower than the accepted criteria (RSD ≤ 2%). The high value of recoveries obtained for VEM indicates that the proposed method was found to be accurate. The stability of VEM solutions was assessed, indicating that the drug remained stable under all relevant conditions. **Conclusions:** Finally, the validated method was successfully applied to evaluate the ability of chitosan-graft-β-cyclodextrin/PVA hydrogels to load and sustain release of VEM. The drug entrapment efficiency (DEE%) was between 65±0.08% and 70±0.05%. **Keywords:** VEMURAFENIB, SUSTAINED RELEASE, DRUG DELIVERY SYSTEM, HPLC-UV METHOD, DRUG TARGETING.

INTRODUCTION

Melanoma, the most aggressive variant of skin cancer, exhibits a rising trend in morbidity and mortality indicators worldwide (1). Consequently, it poses a significant threat to global health, characterized

by limited treatment options and potential side effects. The currently available strategies for the treatment of this type of cancer include surgery, radiotherapy, chemotherapy, immunotherapy and targeted therapy (2). Surgical resection of the tumor with adequate margins is the first-line treatment (3), however a significant risk of incomplete removal of the tumor and occurrence of surgical complications still remains. These can cause a series of pathophysiological processes that can subsequently trigger tumor recurrence and the appearance of metastases induced by surgical intervention (4). Yet, for some patients at stages II, III and IV, surgery alone has limited curative potential (5).

Thus, radiotherapy, chemotherapy, immunotherapy or targeted therapy are often used as adjuvant treatments. Melanoma is a relatively radioresistant tumor, therefore, radiotherapy is widely used as a palliative treatment for metastatic melanoma (6, 7). Chemotherapy remains a therapeutic option for the management of melanoma, but it does not show specificity for tumor cells and, consequently, the accumulation of drugs in the tumor microenvironment is low (8). Thus, the therapeutic benefits are limited (9) and the prevalence of side effects is high, necessitating the exploration of novel treatment alternatives. Immunotherapy employing the four classes of monoclonal antibodies aims to stimulate and activate the immune system (10); nevertheless, a large percentage of patients exhibit both innate and acquired resistance resulting in a lack of response to this therapeutic approach.

Targeted therapy is highly effective in treating advanced melanomas when the cancer cells have certain genetic alterations. Half of all melanomas exhibit changes in the BRAF gene. Vemurafenib (VEM) was the first drug approved by the Food and Drug Administration (FDA) and European Medicines Agency (EMA) for metastatic and unresectable melanoma (11) and Erdheim-Chester disease (ECD) associated with $BRAF^{V600}$ mutation (12). Clinically, VEM is administered orally, but it is accompanied by a high rate of side effects as liver injury, kidney failure, changes in heart rhythm, muscle, bone, and connective tissue disease. In addition, the drug must pass through the acidic environment of the stomach and the intestinal mucus barrier to reach its target. Many active substances are denatured or degraded by stomach acid and some drugs, especially hydrophobic ones, can be easily trapped by mucus and, as a result, are rapidly eliminated before they can be absorbed by the intestine (13). To avoid the gastric and intestinal barrier and to reduce toxicity risks, the potential of topical administration of VEM has been explored (14, 15). The skin serves as a suitable route for the topical delivery of drugs intended for localized effects (16). Administration of vemurafenib by skin is challenging due to its low solubility (17) and the presence of stratum corneum (18), which prevents the penetration of macromolecular drugs into the body. The specialized literature mentions the attempt of topical application of VEM in the form of solid-in-oil nanodispersion as an effective and safe way to deliver VEM but only in the early stage of melanoma (19). Hydrogels are one of the common drug delivery systems for the skin (18, 20) and have garnered high interest due to their remarkable characteristics and applications in the biomedical field during the past decade (21–23). Despite their advantages, there are a number of challenges regarding the poten-

tial use of hydrogels in this field. These challenges refer to drug loading, release control, skin permeability efficiency, and long-term stability. The nature of the polymers in the matrix structure plays an important role, as the functional groups on the polymer surface influence the drug loading capacity and their release behavior, specificity, and safety. Also, the hydrogel's composition significantly influences the drug's transdermal permeation. Considering all the aforementioned factors, we considered necessary to develop a novel formulation in the form of a thermosensitive hydrogel loaded with VEM for localized administration in melanoma treatment. For the synthesis of hydrogels, the use of biopolymers is the most common approach, with chitosan and cyclodextrins serving as versatile carriers for antitumor agents (24).

Chitosan (CS) is a biopolymer used due to its ability to form polymer networks that absorb significant quantities of water and biological fluids (25). These properties are useful in loading drug solutions and absorbing skin exudates. Therefore, CS-based formulations are suitable for cutaneous application due to their hydrophilicity and flexibility (26) and for their attractive biological activity, antitumor, antioxidant, and antimicrobial effects (27, 28). Its cationic polymer can act as a penetration enhancer, being correlated with a certain anticancer activity which is also influenced by its molecular weight and degree of deacetylation (29).

Cyclodextrins (CDs) represent an attractive alternative for the development of carriers for anticancer therapeutics. They were used to design hydrogels as carriers and stabilizers for a large number of drug molecules (30, 31). Among them, β-cyclodextrin (β-CD) is highly advantageous owing to its low cost, effective cavity, lack of toxicity and can enhance the solubility and bioavailability of insoluble drugs (32). The low aqueous solubility of many pharmaceutical developments is an area of constant research. VEM exhibits low aqueous solubility, which implies a poor absorption by the human body. Increasing its solubility is an important factor in increasing its efficacy. In addition, CDs used in the development of transdermal formulations positively influenced the release and/or permeability of the drug, stabilized the drug in the formulation or at the site of absorption, reduced local irritation induced by the drug, and supported the release of the drug from the vehicle (33).

Polyvinyl alcohol (PVA) is frequently utilized in drug delivery due to its superior adhesive characteristics, biocompatibility, and nontoxicity (34). PVA has good chemical stability, forming stable complexes with various drugs to ensure their controlled and sustained release (35). The addition of PVA leads to increased hydrogel porosity, significant mechanical stability, and faster drug release, which may have effective anticancer effects on melanoma cells (36).

The use of hydrogels based on CS, β-CD and PVA could represent an interesting approach to improve the skin release of oncology drugs. In this context, we designed VEM-loaded chitosan-graft-β-cyclodextrin/PVA hydrogels for the local treatment of melanoma (37). β-Cyclodextrin-grafted chitosan functions as the structural component of the hydrogel that increases VEM solubility, controls drug release, and ensures biodegradability and compatibility, while polyvinyl alcohol (PVA) enhances mechanical properties. Enhancing the solubility and stability in water, the pharmacokinetic and pharmaco-

dynamic profiles of VEM, along with the possibility of applying these hydrogels at the tumor site, could change the current therapeutic strategy for melanoma. Monitoring VEM from the sustained-release hydrogel is crucial to ascertain the efficacy of this prospective melanoma treatment.

High performance liquid chromatography (HPLC) has proven to be the predominant technology used in pharmaceutical laboratories worldwide to analyze various drug substances, because is a rapid, automated and high-throughput screening method. Various assays have been reported for the determination of VEM in bulk and biological matrices (38-40). The other reported methods are sensitive, but they are quite complex and time consuming, rendering them unsuitable for routine analysis, as they require expensive or sophisticated instruments. Most refer to the coupling of liquid chromatography (LC) with mass spectrometry (MS) (41–43). It is a useful and robust technique; yet it is not easily accessible and cost-effective routine analysis for pharmaceutical products.

To our knowledge only two research regarding HPLC with ultraviolet (UV) detection methods for determination of VEM in plasma have been reported (44, 45). However, HPLC-UV method has not been reported for the determination of vemurafenib in polymer matrix. To monitor the necessary duration of drug availability (long and short term) and its release profile (continuous or pulsatile), accurate methods of analysis are required.

This study aimed to develop and validate a simple, rapid and effective RP-HPLC method with UV detection for the mutated BRAF inhibitor vemurafenib. Full validation was performed, and the validated method was applied to evaluate the ability of chitosan-graft-β-cyclodextrin/PVA hydrogels to load and release sustained VEM.

MATERIALS AND METHODS

1. Materials

Vemurafenib (VEM), the pharmaceutically active substance incorporated into the hydrogels (99.98% purity) was purchased from Sigma-Aldrich, St. Louis, MO, USA. Formic acid, acetonitrile and methanol of HPLC grade were purchased from Merck (Darmstadt, Germany). Ultrapure water was obtained with Milli-Q® Type 1 Ultrapure Water Systems (Merck, PA, USA). All the other chemicals and solvents used were of analytical grade.

2. Equipment

The high-pressure liquid chromatography (HPLC) system used in this study was Shimadzu Nexera LC-40-XR (Shimadzu, Kyoto, Japan). The system was equipped with a serial dual-plunger pump, an autosampler (SIL 40XR), an SPD-40V series UV-Vis, and an RF-20Axs fluorescence detector (Shimadzu, Kyoto, Japan). Data were recorded and the system was controlled using the Lab Solution DB software 6.106SP1.

3. Method development

3.1. Mobile Phase Optimization

Different mobile phase compositions were tested based on previously published articles (46, 47). Some modifications were implemented (38) to increase applicability under laboratory conditions, and we determined that the mobile phase would consist of a mixture of the following solvents: A (water/formic acid - 99.9/0.1, v/v), B (acetonitrile) and C (methanol). By varying the solvent ratios (30: 55: 15 (MP1); 50: 40: 10(MP2); 40: 55: 5 (MP3)), the appropriate

proportions of the three solvents were studied to obtain an optimal resolution.

3.2. Column Optimization

The method was performed with various C18 columns, such as ODS column (4.6 × 200 mm, 10 µm) (Thermo Scientific, Vantaa, Finland), Xterra (4.6 × 100 mm, 5 µm), and Waters Cortecs column (2.1 × 100 mm, 2.7 µm) obtained from Waters, Milford, MA, US.

3.3. Determination of the wavelength corresponding to maximum absorption (λ max)

The standard solutions of VEM were scanned in the range of 200-400 nm to establish the wavelength at which VEM shows a maximum absorbance.

3.4. Determination of the retention time for VEM

To determine the retention time, two solutions with different VEM concentrations (8 and 12 mg/L) were prepared. A volume of 10 µL of each sample was injected and the retention time was determined.

3.5. Determination of the flow rate

To determine the optimal flow rate, VEM samples with known concentrations of 12 mg/L were prepared. A volume of 10 µL was injected, keeping the other parameters constant but varying the flow rate of the mobile phase.

4. Validation

Upon establishing the optimal analysis conditions, the method was validated by adhering to the following parameters: selectivity, linearity, limit of detection (LOD), limit of quantification (LOQ), precision (system precision, method precision, intermediate precision), and accuracy (48, 49).

4.1. Selectivity

Since the hydrogels contain different components, specificity was attained by comparing the maximum retention time of VEM in the formulations with that in the standard solution.

4.2. Linearity

To determine the calibration curve for VEM, a stock solution of VEM was prepared by dissolving 0.002 g of pure drug in 10 mL of acetonitrile, brought into a 10 mL volumetric flask. Successive dilutions were performed in the 0.78125-100 mg/L range of concentrations. Each standard solution was analyzed in triplicate.

4.3. Limit of detection (LOD) and limit of quantification (LOQ)

Limit of detection and limit of quantification were determined based on the standard deviation of the same concentration and calculated by relations (1) and (2):

$$LOD = 3.3 (SD/S) \quad (1)$$

$$LOQ = 10 (SD/S) \quad (2)$$

where, SD - standard deviation of the response of the curve, and S - Slope.

4.4. System Suitability

Chromatographic system suitability study was done by injecting 6 times consecutively 10 mg/L of VEM standard solution. Injection repeatability, reflected in the invariability of both peak area and retention times, defined the accuracy of the system. The capacity factor, tailing factor, and theoretical plates were also evaluated.

4.5. Method precision

It was done by estimating the corresponding responses three times on the same day and on three different days (first, second, and fifth day) for three different VEM concentration levels (40, 50, 60 mg/L). Each concentration level was analyzed in triplicate.

4.6. Accuracy

To determine the accuracy (precision) of the HPLC method for determining VEM,

the addition method was used: in a solution containing a known amount of standard, volumes of VEM solution were introduced to obtain concentrations of 80%, 100% and 120% compared to the concentration of the solution that was tested (50 mg/L). For each concentration level, three samples were prepared and analyzed, experimentally measuring the peak areas. The recovery was determined as a percentage of the theoretical concentration value.

4.7. Robustness

The robustness was studied by testing the influence of small changes in flow rate (±0.2 mL/min), wavelength (±2 nm), and temperature (±2°C).

4.8. Stability study

Freeze-thaw, short-term, and long-term stabilities of vemurafenib were determined according to the FDA guidelines (48,50,51). The stability of the VEM solution was assessed by comparing the area for the standard solution preserved for various time intervals with the freshly prepared standard. For this study the low and high concentration from the calibration curve were used. The responses of VEM from the stock solutions in mobile phase after 24 h at ambient temperature and after 3 months of storage in the freezer (-30°C) were compared in triplicate to fresh stock solutions.

5. The HPLC-UV conditions for sample analysis

The chromatographic separation was carried out using a Waters Cortecs C18 column (2.1 × 100 mm, 2.7 μm). The column temperature was SET at 40°C. The mobile phase was a mixture of: A (water/formic acid - 99.9/0.1, v/v), B (acetonitrile) and C (methanol) in a ratio of 40: 55: 5 (v/v/v). The elution was set at 1 mL/min in isocratic mode. The detection of VEM was performed in UV at λmax = 252 nm. The injection sample amount was 10 μL. The quantitative and qualitative analysis of VEM was based on its retention time and peak areas, respectively.

6. Application to hydrogels' characterization

The validated method was used to evaluate the chitosan-graft-β-cyclodextrin/PVA hydrogels designed as carriers for the controlled release of vemurafenib.

6.1. Sample preparation

Hydrogels were prepared by mixing the active substance solution with the vehicle solution as presented in our previous study (37).

6.2. Drug loading capacity (DL) and drug entrapment efficiency (DEE%) of the formulations.

To quantify VEM content from the carrier, we weighed the hydrogel samples, dissolved them in a 50/50 (v/v) methanol/acetonitrile mixture in 2 mL capacity vials, and centrifuged them for 24 hours. The supernatant was collected and filtered through a 0.22 μm filter. Then a volume of 10 μL of each sample was injected and analyzed using the HPLC method with UV-Vis detection at 252 nm. The DL capacity was calculated using Equation (3) derived from the calibration curve:

$$y = 45988 \cdot x + 11405 \quad (3)$$

The DEE% of VEM from the hydrogel was calculated with Equation (4):

$$DEE = \text{Actual VEM content loaded in the matrix/Theoretical VEM content} \times 100 \quad (4)$$

Determinations were made in triplicate, and results were reported as the mean of three independent experiments ± SD.

6.3. *In vitro* drug release studies and drug release kinetics

Drug release study of pure VEM and

VEM from hydrogel was conducted by the dialysis membrane method. PBS pH = 6.8 was used as the release medium, maintained at 37 ± 0.5°C under continuous stirring at 50 rpm (52). An aliquot of 1 ml was collected at predetermined intervals and replaced with fresh PBS solution. The drug quantification in each withdrawn sample was done by the HPLC method, as aforementioned. The concentration of VEM in each sample was estimated using the equation obtained from the calibration curve. The experiment was conducted three times, and the mean value was calculated. The cumulative quantity that was released was approximated as a percentage using the concentrations that were determined. The release profiles were fitted to various kinetic models for determining the release mechanism.

7. Statistical Analysis

The statistical analysis of all experimental data was conducted using *IBM SPSS Statistics 25 software*. The data were represented as the mean value accompanied by the standard deviation (SD). One-way Analysis of variance (ANOVA) was used, followed by a post hoc test (Tukey's HSD test), to establish the statistical significance of the observed differences. The predetermined threshold of significance was set at $p \leq 0.05$.

RESULTS

1. Optimization of chromatographic conditions

The method development procedure for drug quantification must follow some critical steps in order to be fully completed and accepted. It is important to develop a simple, rapid, reproducible, and sensitive method for VEM quantification. The following parameters were examined for the optimization of HPLC-UV analysis of VEM from the hydrogel: column, mobile phase, flow, retention time, and wavelength (53, 54).

When selecting the mobile phase, its participation in the separation process along with the stationary phase was considered (55). By varying the solvent ratios, convenient proportions of the three solvents, water/formic acid - 99.9/0.1 (v/v), acetonitrile, and methanol, were established to allow for optimal resolution. To further improve the peak shape, formic acid was added.

According to data presented in fig. 1, it was established that the best mobile phase with less retention time and a larger peak area was a mixture of water/formic acid - 99.9/0.1 (v/v), acetonitrile, and methanol in the ratio of 40: 55: 5 (v/v/v). Altering this ratio would result in a reduction in both the area and height of the peak, thereby diminishing the method's sensitivity. The analyte in isocratic elution was controlled by varying the mobile phase composition. The percentage of organic solvent in the mobile phase influenced the retention time of the analyte and significantly impacted selectivity (56). Regarding the mobile phase elution program, an isocratic system was optimal for VEM separation.

The C18 column is recommended for reversed-phase analysis. VEM separation was attempted with C18 columns packed with particles of different sizes. The ODS columns with the particle size of 10 μm did not effectively separate VEM. The C18 column with smaller particle sizes such as Xterra C18 (250 mm × 4 mm, 5 mm) gave partial separation. Waters CORTECS C18 column (2.1 × 100 mm, 2.7 μm) was found to be ideal, providing excellent peak shape and resolution at a flow rate of 1.0 mL/min. Since the retention time of VEM was also adequate, the column was selected as opti-

mal for conducting the experiments. Another HPLC-UV method described by Zheng *et al.* (44) for simultaneous quantification of vemurafenib and erlotinib in plasma used a C8 Xterra® MS column (250 mm×4.6 mm, 5 µm).

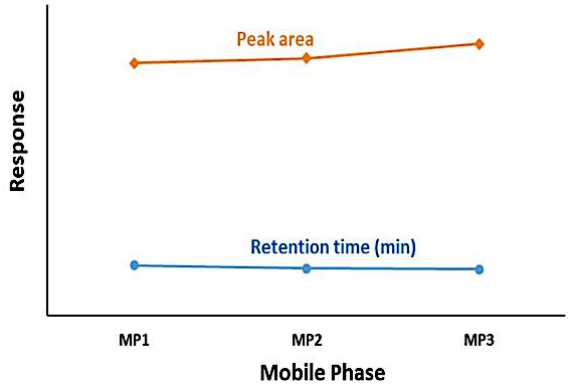

Fig. 1. The effect of mobile phase content to peak area and the retention time of VEM

Based on literature data, we chose 40°C as the working temperature (57). Only one study reported a column temperature of 50°C (44).

Two samples of VEM with different concentrations (8 and 12 mg/L) were analyzed to determine the retention time (T_r). The obtained chromatograms are reproduced in figure 2. The retention time for the analyzed samples was 6 min. The acceptance criteria states that a peak should appear at the retention time, but with different areas depending on the concentration.

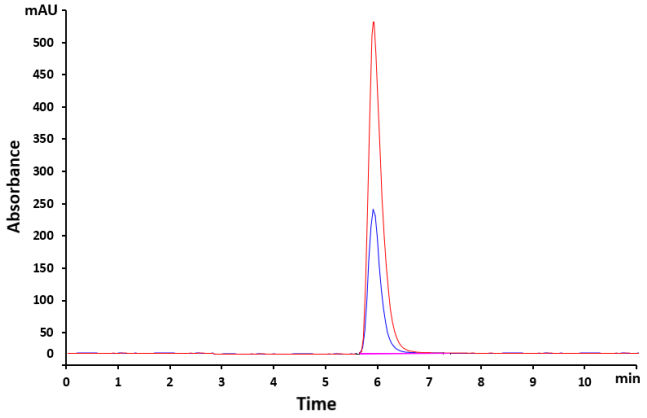

Fig. 2. Overlaid chromatograms of VEM samples with concentrations of 8 and 12 mg/L

The influence of the mobile phase flow rate on peak normalization was studied. To achieve optimal separation and to minimize the total analytical time, flow rates ranging from 0.5 to 2 mL/min were tested. It was observed that at identical concentrations, a

reduction in flow rate resulted in an increased retention time along with a decrease in signal intensity. Conversely, when the flow rate was increased, a decrease in the intensity of the chromatographic peak was observed, although the retention time remained relatively unchanged (fig. 3). All this caused a decrease in the sensitivity of the method. The negative effect would also affect the calculation of LOD and LOQ, which are performance parameters of the method. According to third figure the optimum flow rate was 1mL/min.

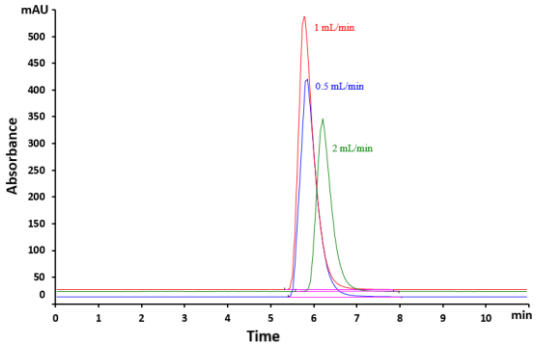

Fig. 3. Overlaid chromatograms of VEM samples with 12 mg/L concentration at different flow rates

We selected the UV detection coupling because, from an analytical perspective, it is a gold standard analytical technology in the pharmaceutical industry (58). The optimal wavelength for VEM was decided after recording the spectrum by the UV detector over the range from 190 to 400 nm. Based on the result (fig. 4), a maximum absorbance for VEM was observed at a wavelength of 252 nm, a finding corroborated by Vakhariya *et al*. (39). This value was used for all validation tests and practical applications. Other studies reported for vemurafenib a maximum absorbance at 307 nm (59), 310 nm (13) and 249 nm (44), respectively.

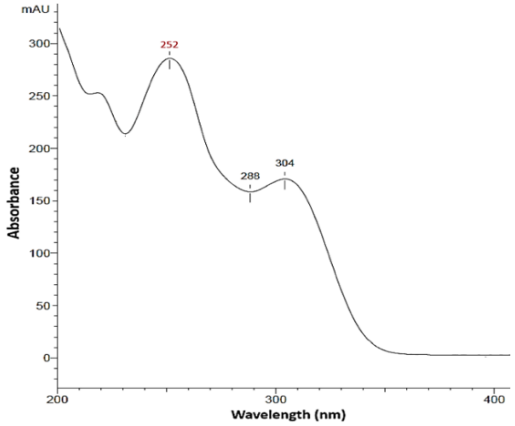

Fig. 4. Absorption spectra of VEM

2. Validation

2.1. Selectivity

The developed method was tested for possible interferences due to the polymer matrix. Six samples were analyzed to investigate the behavior of the matrix components. fig. 5 illustrates that no overlapping peaks were detected at the retention times of the VEM. The retention time of VEM from the sample peak was compared with that of the reference substance. The difference between the two retention times should be ±5% (49). It was found that the retention time of VEM from the sample was 6.02 min, and of VEM for the reference solution was 6.0 min. The proposed method was selective as it effectively separates the peak corresponding to vemurafenib.

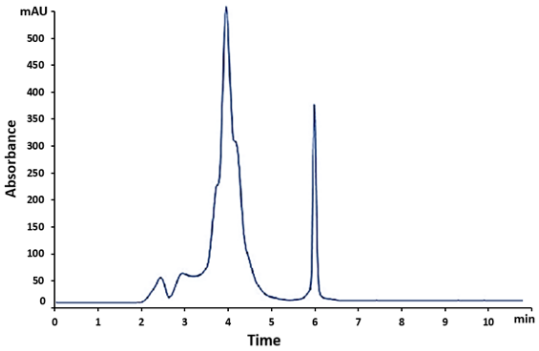

Fig. 5. Sample chromatogram for stability study

2.2. System Suitability

According to the validation guidelines, it is necessary to assess the performance of both the HPLC analytical instrument and the method prior to their application (49). System suitability must be performed before and throughout all regulated assays. System precision was studied by analyzing a number of 6 successive measurements of the same sample (10 mg/L). In this test, the following parameters were investigated: Resolution (R), repeatability (RSD - relative standard deviations - of peak response and retention time), column throughput (N), and tailing factor (T). Considering the values presented in first table, it can be stated that the system was eligible.

TABLE I

System suitability test for VEM

System Suitability Parameter	Acceptance Criteria	Results
Injection Precision for Retention Time (Min)	RSD ≤ 1%	RSD = 0.97
Injection Precision for Peak Area	RSD ≤ 1%	RSD = 0.91
USP Tailing Factor (T)	T ≤ 2.0	1.15*±0.06
Capacity Factor (K)	K ≥ 2.0	7.02*±0.15
Theoretical Plates (N)	N ≥ 2000	5562*±0.02

*Mean of six determinations

2.3. Linearity, LOD, LOQ

To have a robust calibration line, a series of three replicates of each standard was analyzed using the developed method. To study the linear relationship between concentration of VEM (independent variable) and area (dependent variable), we used a least squares method (60). The calibration graph was constructed in the range 0.78-100 mg/L (tab. II and fig. 6). The regression equation was y = 45988·x + 11405, where **y** denotes peak area and **x** the concentration of VEM (mg/L). The linearity of the method was excellent as evidenced by the value of the correlation coefficient (r^2 = 0.9999). The response linearity is verified if the correlation coefficient is 0.99 or greater (54). Also, the Fischer Test showed that $F_{calculated}$ = 19840.115 was greater than $F_{tabulated}$ = 242.98 for a risk of 5% and 11 degrees of freedom, so the correlation ratio between the factorial variable (concentration) and the outcome variable (peak area) is significant. Limit of detection (LOD) and limit of quantification (LOQ) were also performed for VEM with the following results: LOD = 0.5 mg/L and LOQ = 0.75 mg/L. We chose to determine the LOD and LOQ based on the calibration curve because it is more scientifically satisfactory. The LOQ of the present study is 1.66 times lower than that of another previous HPLC-UV method (44) and approximately 4-fold higher than that previously reported with the LC-MS/MS method (38).

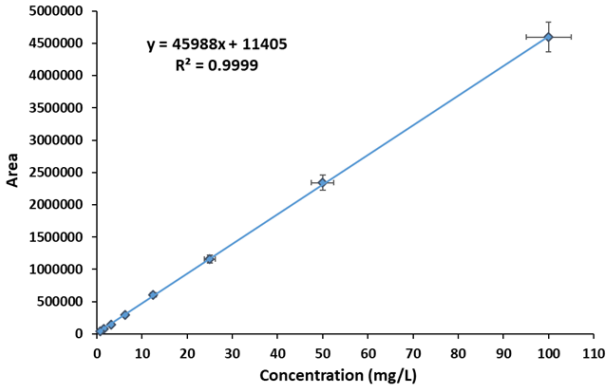

Fig. 6. Calibration graph for VEM over the range of 0.78-100 mg/L (area mean ± SD, n = 3); SD: Standard Deviation

TABLE II

Calibration data for the range 0.78-100 mg/L VEM.

No.	VEM (mg/L)	Area mean ± SD (n = 3)
1.	0.78	37776
2.	1.5625	78257
3.	3.125	146193

2.4. Intra- and Inter-Day Accuracy and Precision

The obtained accuracy and precision data are summarized in tab. III. The %RSD values found in the precision study (RSD < 2%) showed that the proposed method provides acceptable intra- and inter-day variations for VEM determination. To estimate the accuracy, the recovery was determined for a number of three samples at three different concentration levels. The proposed analysis method was accurate because the maximum value of RSD% was less than 2% and the recovery efficiency across the entire investigation range was within the range of 99.45-100.01%.

TABLE III

Precision and accuracy of VEM determination

Theoretical concentration of VEM (mg/L)	Accuracy		Precision			
	Mean recovered conc. of VEM	Mean % recovery	Intra-day		Inter-day	
			Mean*±SD	%RSD	Mean*±SD	%RSD
40	39.78	99.45	40.98±0.3141	0.71	41.08±0.3401	0.68
50	50.05	100.10	50.12±0.2856	0.67	50.06±0.2536	0.63
75	75.01	100.01	75.08±0.3452	0.78	75.02±0.3452	0.73

*Each value is represented as a mean ± SD of observations;
SD: Standard Deviation; RSD: Relative Standard Deviation.

2.5. Robustness

The data obtained for the robustness study are presented in tab. IV. The results showed that there were no significant changes in the chromatographic pattern when the above modifications were made in the experimental condition (the %RSD values were < 3). Therefore, the method was found to be robust with respect to variability in all robust conditions.

TABLE IV

Robustness results for VEM

Parameter	Variation	Retention time (min)	Theoretical Plates	Tailing Factor
Flow Rate	0.8 mL/min	6.23	5492	1.08
	1 mL/min	6.01	5547	1.12
	1.2 mL/min	5.98	5562	1.12
Wavelength	250 nm	6.03	5649	1.11
	252 nm	6.01	5598	1.10
	254 nm	5.99	5697	1.06
Temperature	38°C	6.02	5789	1.13
	40°C	6.00	5856	1.02
	42°C	6.02	5698	1.03

2.6. VEM solution's stability

The results of the stability study of VEM in mobile phase after different storage procedures are summarized in table V. No losses greater than 6.3% were recorded and the deviations found had low standard deviations. The samples could be submitted to further analysis without suffering degradation, the peak area values for VEM being relatively constant. The stability results can be considered satisfactory for the validation and are consistent with those previously reported for vemurafenib (38, 40, 44).

TABLE V.

Stability data (recovery [%]; ± SD; n = 4) of vemurafenib

Conditions	High concentration	Low concentration
24 hrs. at ambient temperature	101.5 ± 1.3	93.7 ± 0.6
3 free-thaw cycles	105.3 ± 1.6	94.8 ± 2.3
3 month -30°C	102.5 ± 1.8	97.3 ± 3.8

DISCUSSION

To evaluate the performance of the developed method, it was compared with other HPLC methods documented in the literature (tab. VI). Methods coupled with mass spectrometry (38, 41) provide superior sensitivity; nonetheless, they are more complex and require costly and advanced apparatus, rendering them impractical for routine analysis. Thus, it was observed that the linear range was close to other methods (38), and the LOQ had a lower value compared to some data in the literature (44, 57) but it was fairly close to that reported with LC-MS/MS (38, 41). Analysis time was similar to that of some methods (44, 61). Most methods used C18 columns and isocratic elution at a flow rate of 1 mL/min. The mobile phase in most cases was a mixture of solvents represented by water-acetonitrile, water-methanol or methanol-acetonitrile in various proportions. Unlike other methods that determine VEM in pure form and from pharmaceutical and biological products, our method determined the drug substance in a polymer matrix.

TABLE VI.

Comparison of the performed method with other HPLC methods

2.7. The capacity of hydrogels in loading and releasing VEM

To show the applicability of the new method after the validation procedure, we investigated the ability of CS-g-β-CD/PVA hydrogels to load and release VEM sustainably. Drug loading has a significant impact on drug release from transdermal systems. The higher drug loading decreases the rate of diffusion to 50%. Lower drug

loading leads to faster drug release.

The drug loading capacity (DL) of the developed formulations, namely CS-g-β-CD/PVA 25/70/5 and CS-g-β-CD/PVA 20/75/5, exhibited 5.7146 μg/mg and 5.7672 μg/mg VEM, respectively. The drug loading process of polymeric networks presented an influence dependent on the composition of hydrogels. It was observed an increase in the networks loading capacity with the decreasing of chitosan content.

The drug entrapment efficiency (DEE%) was between 65±0.08% and 70±0.05%. Those results indicated that both hydrogels exhibited very good DL and DEE% capacity, in line with previous evidence obtained for VEM (13). The exact amounts and loading efficiencies are presented in fig. 7a and 7b. The evaluation of dosage content homogeneity for topical transdermal preparations is mandated by the United States Pharmacopeia, which sets a maximum acceptability value of ±15% (63).

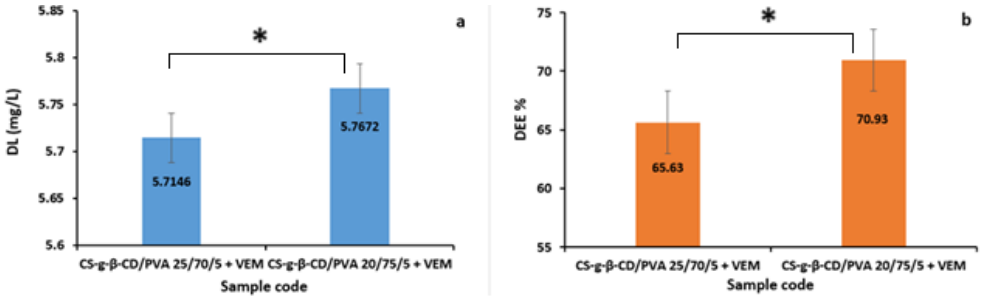

Fig. 7. DL capacity **(a)** and DEE% of hydrogels; **(b)** (mean ± SD, n=3) (* $p < 0.05$)

2.8. In Vitro Drug Release Analysis

CS-g-β-CD/PVA hydrogels with different mass ratios were studied in terms of their VEM release capacity by immersion in the release medium (phosphate buffer solution with pH = 6.8, at 37°C) using the validated HPLC method. The calculation of the amount of drug released was performed based on the equation of the calibration curve. The VEM release profiles under conditions that mimic the biological environment from polymer matrices are represented in fig. 8. The results indicated the prolonged release of VEM from the studied hydrogels when compared to the release of VEM from an industrial product. It was also found that by the increasing the CS concentration in polymer matrix decreased the VEM release rate from the matrix tablets.

According to fig. 8, the release process exhibited a relatively equally intense "burst effect" for the two systems studied. In the first 7 h, CS-g-β-CD/PVA+VEM 20/75/5 releasing around 61% and CS-g-β-CD/PVA+VEM 25/70/5 around 65%. The burst release of VEM might be determined by the presence of drug trapped on the hydrogel surface during the preparation process (64). After that, the release of the drug progressively increases up to 10 hours for both matrices studied, reaching 87% and 91% of the incorporated VEM amount. This stage was followed by a slightly linear sustained release profile with the release of 10% and 12% of the incorporated drug. The slow drug release could be due to poor solubility of drug. At the end of the dissolution test, the amount of VEM in CS-g-β-CD/PVA+VEM 20/75/5 is the lowest.

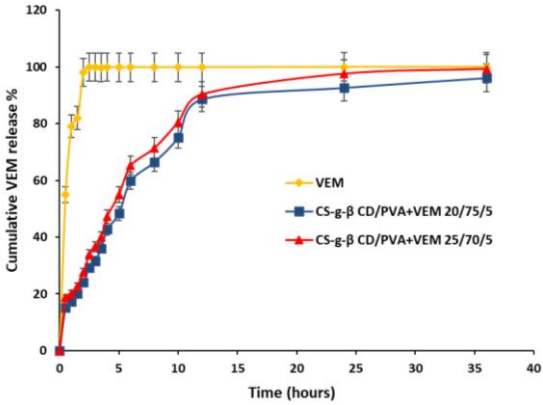

Fig. 8. Drug release of VEM. Data are mean ± SD within ±2 (n = 3)

2.9. Kinetics of in vitro drug release study

To understand the kinetics and the main mechanisms which govern the release of VEM from CH-g-β-CD/PVA hydrogels, the data plotted in fig. 8 were fitted using different kinetic models (65–67). The data are given in tab. VII. The selection of the model that most accurately described the release profile of VEM from the obtained hydrogels was based on the Akaike Information Criterion (AIC) and the r^2 correlation coefficient.

TABLE VII.
Data fitting results of *in vitro* VEM release profile from hydrogels

Kinetic Model	Parameters	Sample	
		CS-g-β-CD/ PVA 25/70/5	CS-g-β-CD/ PVA 20/75/5
Zero order	K_0	4.588	4.302
	r^2	0.668	0.496
	AIC	148.420	144.043
First order	K	0.155	0.156
	r^2	0.895	0.839
	AIC	6.887	14.342
Higuchi	K_H	27.513	29.468
	r^2	0.923	0.865
	AIC	125.549	134.365
Korsmeyer-Peppas	K_P	45.991	48.097
	n	0.372	0.293
	r^2	0.958	0.897
	AIC	103.589	108.123

K_0 - constant of zero order release rate; K - constant of first order release rate; K_H - constant of Higuchi model release rate; K_P - constant of Korsmeyer-Peppas model release rate; n = diffusion exponent.

Values of r^2 and values of AIC range between 0.983-0.991 and 103.589-148.420, respectively (tab. VII). For r^2, the value should be as close as possible to 1 to demonstrate a yield as good as possible for a formulation and the AIC must have minimum values (23, 68). In our study the values of r^2 and AIC indicated that the obtained hydrogels did not follow an ideal zero-order kinetics, nor a first-order kinetics. The r^2 values for the Higuchi and Korsmeyer-Peppas models did not differ significantly. The difference was given by the lower AIC values for the Korsmeyer-Peppas model. This indicated that the release of VEM from hydrogels occurred through the diffusion phenomenon (69). The diffusion mechanisms were indicated by the values of the diffusion exponent (n) in the Korsmeyer-Peppas equation. The values of n indicated a release by Fickian diffusion for VEM.

The choice of the optimal model for drug release could also be determined if there was an initial release of the active substance of 60%. Taking this into account, Korsmeyer-Peppas was the most effective and best-fitting model for release of VEM based on the data collected after 40 h. Over time, the release profile of VEM from different pharmaceutical forms has been associated with the Korsmeyer-Peppas model.

CONCLUSIONS

In the present study, a new, simple, rapid and validated HPLC method with UV detection was developed for vemurafenib determination in polymer matrices.

The advantages of our method include reduced analysis time, a simple procedure for sample preparation, specificity, and the ability to separate the drug from polymeric matrices, without the need of extraction. It also observed that there was no interference from the hydrogel's components for the determination of the VEM. The recovery percentage for the determination of VEM in polymer matrix had a value close to 100% and was similar to other methods documented in the literature. The obtained results during the *in vitro* dissolution test indicated the prolonged release of VEM from the studied hydrogels compared to the release of VEM from an industrial product. The method is suitable for routine analysis of VEM in bulk, in tablet dosage forms or hydrogels and can be also used during *in vitro* studies. The high sensitivity of the method allows its application in further studies of transdermal release or permeability of active ingredients in hydrogels.

STRESS DISTRIBUTION IN PERIODONTALLY COMPROMISED MANDIBULAR MOLARS UNDER ASYMMETRIC LOADING: A THREE-DIMENSIONAL FINITE ELEMENT STUDY (Abstract): Periodontal disease alters the biomechanical stability of the supporting tissues, predisposing them to damage under occlusal overload. This study aims to use finite element analysis (FEA) to evaluate the effect of traumatic occlusal forces on a mandibular second molar with compromised periodontal support. **Materials and methods**: A three-dimensional FEA model was constructed from CT data and subjected to symmetrical and asymmetrical occlusal loads, ranging from 500 N to 1000 N, with variations in tooth inclination. **Results**: The results showed that axial stress and maximum displacement increased proportionally with force intensity, with the highest values observed under asymmetric loading in mesial inclined teeth with alveolar bone loss. In contrast, symmetrical loading on a well-aligned tooth in normal bone conditions generated minimal stresses. **Conclusions:** These findings highlight the critical role of occlusal force distribution in periodontal biomechanics and confirm that traumatic occlusion may accelerate tissue breakdown in compromised periodontium. **Key words:** FINITE ELEMENT ANALYSIS, TRAUMATIC OCCLUSAL FORCES, PERIODONTAL BIOMECHANICS, MANDIBULAR MOLAR, STRESS DISTRIBUTION.

INTRODUCTION

Finite element analysis (FEA) has emerged as a powerful computational tool to study stress distribution and deformation in biological structures. Unlike conventional experimental models, FEA allows for three-dimensional simulation of complex anatomical geometries and material properties, enabling the investigation of biomechanical behavior under controlled loading conditions (1). In periodontology, FEA has been widely applied to evaluate stress transmission in alveolar bone, periodontal ligament, and restorative materials, offering valuable insights into the interactions between mechanical forces and biological tissues (2).

Applying FEA to the study of traumatized and diseased periodontal tissues offers the opportunity to quantify how occlusal forces contribute to pathological stress concentrations. Such knowledge is critical for clarifying the role of traumatic occlusion as a modifying factor in periodontitis and for guiding clinical decision-making in occlusal adjustment, splinting, and prosthetic rehabilitation (3). The biomechanical analysis of molars provides

insights into dento-periodontal functional patterns during masti-cation and thus allows the evaluation of masticatory function (4).

Occlusal overload has been widely debated as a contributing factor in the progression of periodontal breakdown. While inflammation is the primary etiologic agent in periodontitis, mechanical stresses generated by traumatic occlusal forces can exacerbate tissue destruction, particularly in already compromised periodontal structures (5). Understanding how these forces distribute within the dento-periodontal complex is therefore critical for clarifying the role of occlusal trauma as a modifying factor in periodontal disease progression (6).

To accurately define the stress field of a molar under occlusal loading, it is essential to construct a model that incorporates the geometry of the structure, the properties of the tissues, and the forces acting on the dento-periodontal system (7).

The aim of the present study was to investigate, through finite element analysis, the axial stresses along the direction of force as well as the displacements resulting from the application of occlusal forces of different magnitudes on a mandibular second molar model.

MATERIALS AND METHODS

A three-dimensional finite element analysis model of the mandibular right second molar was constructed based on anatomical parameters described in the literature. The model incorporated the following dimensions: coronal length 7 mm, root length 13 mm, mesiodistal crown diameter 10.5 mm, cervical mesiodistal crown diameter 8 mm, buccolingual crown diameter 10 mm, and cervical buccolingual crown diameter 9 mm. Geometric reconstruction ensured that the tooth and surrounding structures were represented with high fidelity to their anatomical proportions, thereby providing realistic boundary conditions for stress analysis (fig. 1).

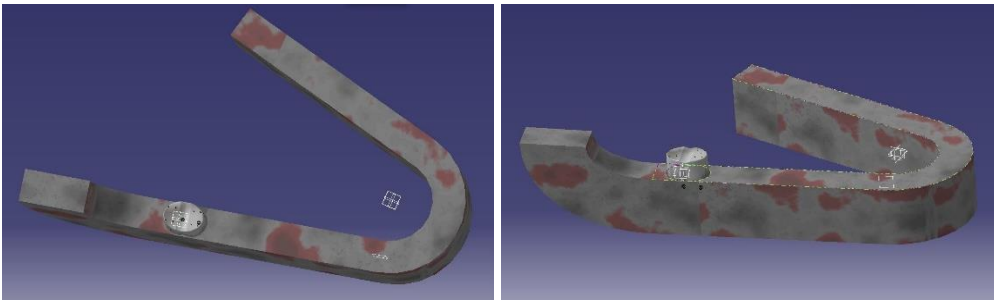

Fig. 1. Three-dimensional finite element analysis model of the mandibular right second molar; superior view (left); latero-superior view (right)

The biomechanical properties of the periodontal tissues were derived from experimental data reported in previous studies, with values assigned to enamel, dentin, pulp, periodontal ligament, and alveolar bone. For the purpose of simplification, and in line with established modeling practice, each tissue was modeled as a homogeneous, isotropic, and linearly elastic material. This approach allows for reliable stress mapping while avoiding unnecessary complexity in material heterogeneity.

The 3D structure was designed and

processed in Catia V5 (Dassault Systèmes, France). The final mesh consisted of 20,875 nodes and 16,616 parabolic prismatic elements, which provided adequate discretization of the model. The element size and density were optimized to achieve a balance between computational efficiency and accuracy of stress prediction. The element dimensions were as follows: mandible - 7.935 mm with a precision of 1.27 mm; periodontal ligament - 0.892 mm with a precision of 0.143 mm; and tooth - 1.27 mm with a precision of 0.203 mm. The mesh refinement was specifically enhanced at the tooth-ligament-bone interfaces, where stress concentrations were anticipated.

Rigid boundary conditions were applied at the base of the alveolar segment to simulate the anchorage of the jawbone. Loading conditions included vertical forces of 500 N, 650 N, 800 N, and 1000 N, applied at occlusal contact areas to represent different intensities of functional and traumatic occlusal loads. The interfaces between dentin and periodontal ligament, periodontal ligament and alveolar bone, enamel and dentin, and dentin and pulp were modeled as perfectly bonded, ensuring no relative displacement between adjacent tissues.

The loading scenarios were designed to simulate both physiological and supraphysiological conditions, enabling comparison between normal mastication forces and potentially traumatic forces. Stress distribution was calculated and expressed as von Mises stress, which is widely used as a criterion to evaluate the biomechanical performance of dental and periodontal structures under complex loading. In addition to stress analysis, displacement vectors were also recorded to evaluate the deformation patterns of the tooth and supporting tissues under different magnitudes of occlusal force.

RESULTS

The application of a symmetrical and uniform occlusal load on a compromised periodontium (simulated bone loss of 5.5 mm) in a non-tilted mandibular second molar produced the following outcomes (tab. I).

TABLE I.

Measurements in bone affected by periodontal disease, simulated as horizontal bone loss of 5.5 mm. The occlusal force was applied symmetrically and uniformly on the occlusal surface of the tooth, without angulation

No.	Occlusal force	*σech* von Mises [mPa]	f (movement) [mm]	*Σdirection of force* [MPa]
1	500 N	324	0.298	139
2	650 N	418	0.388	180
3	800 N	515	0.478	221
4	1000 N	644	0.598	276
$\bar{x}$ ± SD		475.25 ± 136.88	0.441 ± 0.128	204.0 ± 58.52
f = maximal displacement; *σc* = axial stress in the loading direction				

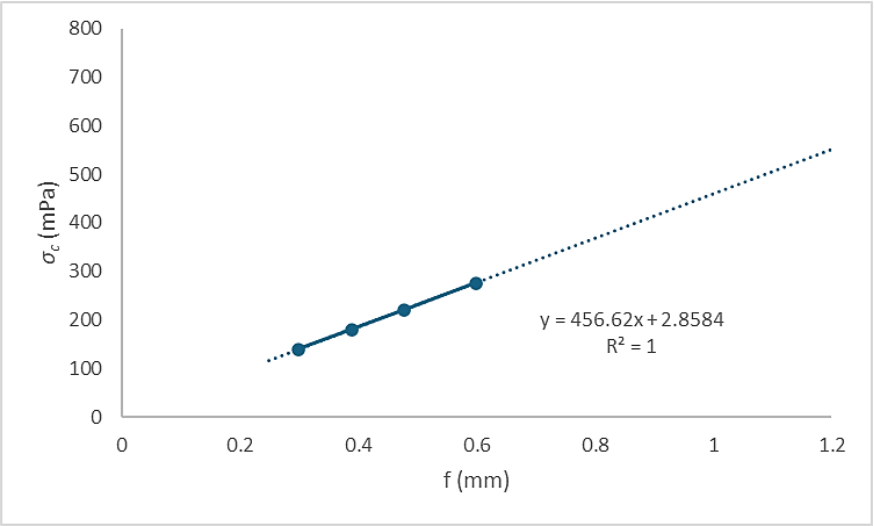

Fig. 2. Correlation between maximum displacement (f) and axial stress (σ_c) in the loading direction in bone affected by periodontal disease.

The axial stress along the direction of loading ranged from 139 to 276 mPa, with a mean value of 204.0 ± 58.52 mPa. A strong positive correlation was observed between occlusal force magnitude and axial stress (r = +0.999; p = 0.001), indicating that stress increased proportionally with the intensity of applied forces. Similarly, axial stress showed a significant correlation with maximum displacement values (r = +0.999; p = 0.001), demonstrating that higher occlusal loads not only increased stress concentration but also amplified tooth movement within the compromised periodontal support. The trendline was linear (R2 = 1), with a slope of 456.62, suggesting a perfect fit of the linear model to the data points (fig. 2).

Simulation of a clinical scenario with 20 degrees mesial inclination of the mandibular second molar, in the context of a compromised periodontium with 5.5 mm horizontal bone loss and the application of unilateral, asymmetric distal forces, yielded the following results (tab. II).

The axial stress in the loading direction ranged from 311 to 622 mPa, with a mean value of 458.75 ± 132.94 mPa. Axial stress in the loading direction increased significantly with the magnitude of the applied occlusal force (r = +0.995; p = 0.006). Axial stress in the loading direction also increased significantly with maximum displacement (r = +0.996; p = 0.006). In this case trendline was also linear (R^2 = 1), but the slope increased to 617.58, suggesting an accentuated displacement in comparison to the perpendicular force action (fig. 2).

The mean level of maximum displacement showed statistically significant differences depending on bone type (p = 0.001). The lowest mean displacement was observed in unaffected bone with a 20 degrees mesial inclined molar (0.027 ± 0.008 mm; range: 0.019 - 0.037 mm). The highest mean displacement was recorded in unaffected bone with a non-tilted molar under symmetrical and uniform distal occlusal loading (9.885 ± 2.854 mm; range: 6.71-13.40 mm).

TABLE II.

Measurements in bone affected by periodontal disease. The occlusal force was asymmetrically applied on the distal surface; molar mesially inclined at 20 degrees

No.	Occlusal force	σ_{ech} von Mises [mPa]	f (movement) [mm]	*Σ direction of force* [MPa]
1	500 N	339	0.506	311
2	650 N	441	0.658	404
3	800 N	542	0.809	498
4	1000 N	678	1.01	622
$\bar{x}$ ± SD		500.0 ± 144.74	0.746 ± 0.215	458.75 ± 132.94
f = maximal displacement; σ_c = axial stress in the loading direction				

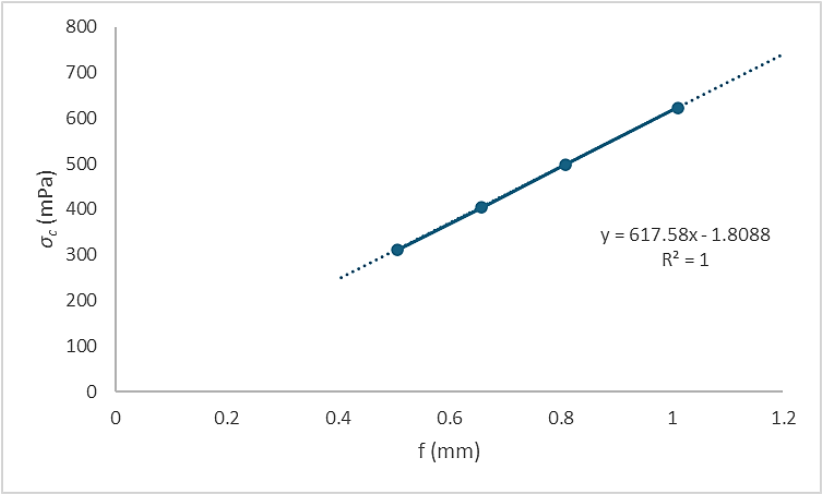

Fig. 3. Correlation between maximum displacement (f) and axial stress (σ_c) in the loading direction in bone affected by periodontal disease; asymmetric occlusal force applied on the distal surface; molar mesially inclined at 20 degrees.

The mean level of axial stress in the loading direction showed statistically significant differences across bone types (p = 0.001). The highest mean value was recorded in bone affected by periodontal disease with 5.5 mm horizontal bone loss, under asymmetric distal occlusal loading and 20 degrees mesial inclination of the molar (458.75±132.94 mPa; range: 311-622 mPa).

The maximum displacements observed under different loading intensities and tooth angulations showed the lowest values for an inclined molar subjected to eccentric force application, and the highest values for a properly aligned tooth with forces distributed across the entire occlusal surface (tab. III).

TABLE III.
Descriptive indicators of maximum displacement (mm) compared across affected bone.

Type of bone	N	Mean	Std. Dev.	Std. Error	Confidence interval 95%		Min	Max
					-95%CI	+95%CI		
Affected bone, non-tilted molar, symmetrical occlusal force	4	0.441	0.128	0.064	0.237	0.644	0.298	0.598
Affected bone, molar mesially inclined at 20°, symmetrical occlusal force.	4	0.746	0.215	0.108	0.403	1.088	0.506	1.010

DISCUSSION

In the present study, a finite element model based on CT images of the mandibular second molar was established to explore the effects of progressively increasing excessive occlusal forces on dental stress. The regions and distribution values of von Mises stress were used to describe the load transfer mechanism. Although this model was developed using CT data from a single volunteer with certain anatomical particularities, the regularities derived from this analysis may be useful for understanding consistent biomechanical patterns of occlusion.

Similar results have been reported in previous studies. Mezzomo *et al*. created a finite element model of a maxillary central incisor and applied a static load of 100 N to the center of the palatal surface (8). Their findings demonstrated that the stress values in the enamel were significantly higher than those in the dentin, with the enamel-cementum junction serving as the boundary (8).

The study conducted by Chen *et al*., using 3D finite element models of different tooth types, investigated the influence of various alveolar bone heights on numerical simulations of tooth mobility and von Mises stress in the presence of periodontitis (9).

The 3D FEA of tooth geometry characteristics and stress relationships under different alveolar bone levels suggested that von Mises stresses may increase as periodontal support decreases. This indicates that teeth are subjected to greater stress when alveolar bone height is reduced, thereby becoming more susceptible to occlusal trauma (9).

Zarrati *et al*. used force sensors to examine differences in tooth mobility between patients with and without periodontal disease (10). They concluded that tooth mobility cannot be attributed solely to the loss of alveolar bone but also results from structural changes within the periodontal apparatus (10). Animal studies reported the simultaneous occurrence of periodontal connective tissue alterations, alveolar bone loss, and increased tooth mobility in animals predisposed to periodontal lesions (11). Animal models have the advantage of experimental inducement of several pathological conditions (12), that could be further evaluated and introduced in simulated mathematical models.

Studies conducted in both humans and

animals have demonstrated an apparent relationship between tooth mobility and periodontitis associated with reduced alveolar bone height. The inflammatory component of periodontal disease represents a critical modifying factor in tissue breakdown and biomechanical stability. Inflammatory mediators such as interleukin-6 (IL-6), tumor necrosis factor-alpha (TNF-α), and interleukin-1 beta (IL-1β) are upregulated in periodontitis and contribute to connective tissue degradation and alveolar bone resorption (13-15). Low-level laser therapy (LLLT) has emerged as a non-invasive therapeutic modality capable of modulating inflammatory responses in various chronic inflammatory conditions, as emphasized by some researchers from our university, more than a decade ago (16). Meanwhile, the anti-inflammatory mechanisms of photon radiation and the involvement of photobiology in contemporary dentistry became an evocated fact in literature (14).

Wang *et al*. further concluded that there is a strong correlation between the amount of alveolar bone and overall tooth stability (17). However, evidence remains limited regarding the relationship between tooth mobility and variations in alveolar bone height across different tooth types analyzed through 3D FEA simulations (17).

Another variable that could influence the theoretical simulated model is represented by local vascularization, prone to high variability at the facial skeleton level. The recognition of anatomical variations in vascular supply is essential for understanding the biomechanical and biological behavior of oral structures under functional stress. Similar to the documented supernumerary fronto-orbital arteries (18), significant anatomical variability has been observed in the arterial branches supplying the maxillary dentition and periodontal tissues. The infraorbital artery (IOA) and the posterior superior alveolar artery (PSAA), both branches of the maxillary artery, demonstrate considerable variation in their course, diameter, and distribution patterns. In a cone beam computed tomography study, the PSAA was visualized in more than 2/3 of cases, with variable distances from the alveolar crest, directly influencing the vascular supply to maxillary molars, premolars, and the surrounding alveolar bone (19). Furthermore, anatomical surveys have documented anastomoses between PSAA and IOA at the premolar level, forming transverse periosteo-mucosal anastomoses that supply the marginal gingiva, interdental papillae, and periodontal ligament through buccal branches penetrating the interdental septum (20). These vascular networks are critical for maintaining tissue integrity and adaptive responses to mechanical loading. While the present study focused on mandibular second molars and their supporting structures, the documented variability in maxillary arterial supply underscores the need for future finite element models incorporating upper teeth to evaluate the interplay between vascular patterns, periodontal biomechanics, and occlusal stress distribution in the maxilla.

Although it is well established that FEA models cannot provide direct practical predictions regarding the effects of external forces on alveolar bone height or on stress distribution, it is nevertheless reasonable to apply external forces to alveolar bone of varying heights in order to evaluate stress distribution patterns (21).

One of the main advantages of FEA studies is the ability to demonstrate numer-

ical stress variations under normo-occlusal, hypo-occlusal, and hyper-occlusal loading conditions. Normal occlusal loads can be applied according to values reported in the literature, and moreover used in conjunction with artificial intelligence models to increase coverage of different scenarios (22). In contrast, hypo- and hyper-functional loads are hypothetical scenarios designed to estimate possible numerical stress values at specific points of static occlusal loading. In reality, there is wide individual variation in occlusal loading on each tooth, depending on factors such as diet, physiological activity, muscular forces, and parafunctional habits (23).

The determination of stress values is therefore a prerequisite for clarifying the role of occlusion in the health and stability of periodontal tissues. Future directions in this field should focus on understanding biological adaptation mechanisms in order to design reliable methods for evaluating the complex structural and functional interactions that define the dento-periodontal system.

CONCLUSIONS

In the present study, we demonstrated that maximal stress occurs when premature, asymmetric occlusal forces act on a mispositioned tooth already compromised by periodontal disease. In contrast, physiological forces applied uniformly and symmetrically across the occlusal surface of a properly aligned tooth within a normal alveolar bone environment generated minimal stress values.

These findings highlight the critical role of masticatory force distribution under different simulated conditions, showing that traumatic occlusal forces with asymmetric loading can produce severe damage to the supporting periodontal tissues.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding.

PERSONALITY TRAITS AND MONEY ATTITUDES AMONG SCHOOLTEACHERS: AN EXPLORATORY PSYCHOLOGICAL ANALYSIS (Abstract). Financial well-being is a multidimensional construct that reflects perceived financial control and security. While it is not directly measured in this study, money attitudes represent an important cognitive-affective component associated with financial well-being. **Materials and methods:** This cross-sectional study examined the relationship between personality traits and money attitude dimensions among 172 schoolteachers from northeastern Romania. The Big Five© plus-short and the Money Attitude Scale (MAS) were applied to assess personality traits and the dimensions of power-prestige, retention-time, distrust and anxiety toward money. **Results:** showed that emotional stability was negatively associated with financial anxiety and distrust, while gender and emotional stability influenced the perception of money as power-prestige. Extraversion, conscientiousness and openness predicted retention-time attitudes. Although the observed correlations were of low intensity, they align with previous research indicating subtle but consistent personality influences on financial cognition. **Conclusions:** These findings suggest that personality traits may shape teachers' money attitudes, with potential relevance for psychological screening and financial awareness programs in educational settings.

INTRODUCTION

Teaching is a profession characterized by complex psychosocial demands that can influence both occupational satisfaction and mental well-being. Teachers often face high workloads, emotional exhaustion, and financial constraints, which may undermine their psychological health and job performance. Among the multiple determinants of well-being, personality traits play a central role in shaping how individuals perceive and cope with work- and finance-related stressors. Financial well-being, although not always explicitly measured, represents a key dimension of overall well-being, reflecting individuals' perceived control, security, and confidence in managing financial demands.

The Five-Factor Model (FFM), or Big Five framework, conceptualizes personality through five broad and stable dimensions: extraversion, agreeableness, conscientious-

ness, emotional stability (the inverse of neuroticism), and openness to experience. These traits have been consistently linked with occupational adjustment, resilience, and mental health outcomes across diverse cultural and professional contexts (1-7). Within educational settings, conscientiousness and emotional stability have been associated with higher job satisfaction and lower burnout (8, 9, 10), while openness and extraversion promote creativity and engagement in teaching.

Beyond the workplace, personality traits also shape financial attitudes and behaviors. Money is not only an economic resource, but a psychosocial symbol linked to power, security, and self-esteem (11). According to Yamauchi and Templer's Money Attitude Scale, four key dimensions capture the cognitive-affective meaning of money: power-prestige, retention-time, distrust, and anxiety (11). Previous research has shown that conscientiousness and openness are associated with prudent financial management, while low emotional stability is related to impulsive spending and financial anxiety (12, 13, 14, 15). However, most evidence derives from general or student populations, with limited attention to teachers—professionals whose financial and psychological well-being are deeply intertwined.

In the educational sector, modest income levels and socio-economic instability can exacerbate stress and anxiety among teachers, especially when combined with emotional or personality-based vulnerabilities. Recent studies have emphasized that financial stress is a significant determinant of teacher mental health, contributing to burnout, absenteeism, and reduced job performance (16, 17, 18, 19). Recent international evidence further confirms that financial strain and economic uncertainty represent significant stressors for teachers, contributing to emotional distress, burnout, and reduced occupational well-being across diverse educational systems (20, 21, 22). These findings highlight the importance of understanding psychological mechanisms, such as personality and money attitudes, that may influence financial well-being and indirectly affect occupational health. Financial well-being should be seen as a psychosocial determinant of mental health (stress, burnout, absenteeism).

Additionally, previous research indicates that financial attitudes vary across the lifespan, reflecting developmental and socio-economic differences. Younger adults often report higher financial anxiety and impulsiveness, whereas older individuals tend to adopt more cautious, future-oriented financial strategies (15, 23, 24). Therefore, age was included in the present study as a control and predictive variable to capture potential generational variations in teachers' financial attitudes.

To our knowledge, no prior study has specifically explored how the Big Five personality traits predict money attitudes among teachers. This research addresses that gap by examining the relationships between personality dimensions, demographic factors, and the four components of money attitudes - power-prestige, retention-time, distrust, and anxiety - in a sample of Romanian teachers. Understanding these associations can inform the development of preventive psychological and financial well-being programs tailored to educational professionals.

The present study aimed to test the following hypotheses:

- (H1) Emotional stability will be negatively associated with power-prestige

- (H2) Extraversion, conscientiousness, and openness will be positively associated with retention-time;
- (H3) Low emotional stability and low conscientiousness will predict higher distrust; and
- (H4) Low emotional stability will predict higher financial anxiety.

Criteria: extraversion, agreeableness, conscientiousness, emotional stability, openness to experience.

MATERIALS AND METHODS

Study design and Participants.

Using the snowball sampling method, a cross-sectional study was conducted among schoolteachers in northeastern Romania. An online questionnaire was created and distributed between February and May 2025 using Google Forms and could only be filled in only after the participants agreed to the informed consent form. The instrument was administered in a research-only, non-clinical context, and participants were clearly informed that the questionnaire did not serve any diagnostic or evaluative purpose. The Big Five© plus-short has been validated for self-administration in online formats in previous Romanian research and was used here in accordance with ethical guidelines for psychological research with non-clinical adult populations. The survey was administered in an anonymous format, ensuring that no personal identifiers were stored, and all responses remained confidential. The teachers were informed about the use of the results and that they could withdraw from study at any time. No incentives were provided to the participants. Continuing to complete the questionnaire indicated the participants' consent to be included in the study. *The inclusion criteria* were teachers who were professionally active in public or private schools and sent questionnaires that were fully filled in. *The exclusion criterion was* the submission of the questionnaires after the deadline. Snowball sampling was selected as a pragmatic approach due to limited centralized access to schoolteacher registries and to facilitate recruitment in a dispersed professional population. Although this non-probability method allowed efficient data collection from active educators, it does not ensure full representativeness of the national teacher population. A total of 172 teachers met the inclusion criteria and were included in the analysis. Of these, 72.1% were female (N = 124) and 27.9% male (N = 48). Participants ranged in age from 19 to 65 years (M = 41.75 ± 12.34), with 36% aged between 19 and 39, 39% between 40 and 50, and 25% between 51 and 65 years. In the Romanian educational system, individuals may begin teaching activities as substitute or trainee teachers from the age of 18-19, particularly in private institutions or in rural schools experiencing staff shortages. Therefore, eligibility to participate was based on *active teaching engagement*, not on formal rank or years of certified teaching service.

Study instruments. An online questionnaire was constructed to assess personality traits and measure money attitudes among schoolteachers. The first part gathered sociodemographic information, such as age and gender. The second part of the questionnaire included several psychological instruments:

1. The Big Five© plus-short (Constantin *et al.*, 2008) was used to assess the five major dimensions of personality: extraversion, agreeableness, conscientiousness, emotional stability, and openness to expe-

rience. (25). The Big Five© plus-short was used to assess the five major dimensions of personality: extraversion, agreeableness, conscientiousness, emotional stability, and openness to experience. The instrument consists of 90 items presented as statements rated on a forced-choice 3-point scale, where 1 = “disagree”, 2 = “partially agree”, and 3 = “agree”. Sample items include: “I enjoy being the center of attention” (extraversion), “I try to maintain harmony in my interactions” (agreeableness), and “I always complete the tasks I start” (conscientiousness). Higher scores reflect a stronger expression of the respective personality trait. The instrument consists of 90 items extracted from the Big Five© plus inventory. The Big –instrument has previously demonstrated satisfactory validity and reliability in Romanian samples, as reported by Constantin *et al.* (2008), confirming its suitability for use in local educational and occupational research. The Cronbach’s alpha internal consistency coefficients obtained for the questionnaire factors were as follows: Extraversion: 0.82; Agreeableness: 0.66; Conscientiousness: 0.75; Emotional stability: 0.85 and Openness to experience: 0.71 (12).

2. The Money Attitude Scale test (MAS; Yamauchi & Templer 1982) was used to identify individuals’ attitudes toward money (11). The scale consists of 29 items designed to evaluate four dimensions of attitudes toward money: power-prestige (9 items; e.g., "Although I should judge people’s success by their actions, I am more influenced by the amount of money they possess"), retention-time (7 items; e.g., "I regularly set money aside for the future"), distrust (7 items; e.g., "It bothers me when I find out I could have got something for a lower price elsewhere"), and anxiety (7 items; e.g., "I spend money to make myself feel better"). Responses were rated on a Likert scale (from 1 = "never" to 7 = "always"). Total scores were calculated for each dimension. The MAS is theoretically grounded in the conceptualization of money as a multidimensional psychological construct associated with power, security, and emotional regulation (11). In addition, research has highlighted the mediating role of money attitudes in the relationship between online behaviors and financial habits (26). Previous international studies have reported acceptable psychometric properties of this scale, and the Cronbach’s alpha coefficients obtained in the present study are consistent with those reported in European samples, supporting its applicability in this context. The Cronbach’s alpha internal consistency coefficients obtained for the scale dimensions are as follows: Power-prestige dimension: 0.71; Retention-time dimension: 0.82; Distrust dimension: 0.70 and Anxiety dimension 0.70.

Statistical analysis. The IBM *Statistical Package for Social Sciences (SPSS) and Statistics for Windows, version 29* (SPSS Inc., Chicago, IL, USA) were used to test the hypotheses (1). The adequacy of the sample size was assessed based on methodological conventions rather than a formal power analysis. For correlational studies in behavioral sciences, sample sizes above 100 are generally considered sufficient to detect medium effect sizes with adequate power (Cohen, 1988; Maxwell, 2000). The present study included 172 participants, exceeding this threshold and thus providing sufficient sensitivity for the intended analyses. Before applying Pearson’s correlation, we inspected the distribution of composite scale scores for skewness and kurtosis and found no severe deviations from

normality. Although the item responses were ordinal, the use of aggregated scale scores is considered acceptable for parametric testing in psychological research, as supported by methodological literature in the field. Therefore, Pearson's correlation was applied, in line with similar studies using the Big Five and MAS scales. Pearson's correlation coefficient was used to test the first four research hypotheses. An exploratory interaction analysis was conducted to test whether the combined effect of personality traits further influences money attitudes (exploratory, no hypothesis pre-registered). The t-test for independent samples was applied to compare group differences. Despite the unequal group sizes, the independent-samples t-test was applied using Levene's correction for unequal variances to ensure the robustness of the gender comparisons. Although no a priori power analysis was conducted, the sample size exceeds the commonly recommended threshold of 30 participants per predictor variable in regression models, suggesting that the study has acceptable power for exploratory analyses. Nevertheless, the statistical power to detect small interaction effects may be limited. To control for potential Type I error due to multiple comparisons, a conservative interpretation threshold was adopted. Only results with $p < 0.01$ were considered meaningful, consistent with exploratory research practices in psychological studies. This approach limits false-positive risk while maintaining reasonable sensitivity to genuine effects. Given the exploratory nature of the study and in line with recommendations for psychological research, associations with theoretical support and $p < 0.01$ were interpreted as robust.

Ethical Approval. The present study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethical Committee, No. 364/ 12.02.2025, Emil Racovita National College, Iași, Romania. Before starting the survey, the respondents were informed about the purpose of the research, the use of the results and confidentiality of the data. Those who agreed to participate filled out the questionnaires distributed online. No incentives were provided to the participants.

Informed Consent Statement.

Informed consent was obtained from all subjects involved in the study.

RESULTS

Pearson's correlation was used to examine the relationship among the research variables. The correlation statistical analysis indicated:

- a positive, low-intensity, and significant association between extraversion and agreeableness ($r = .283$, $p < .001$),
- agreeableness showed positive, low-intensity, and significant correlations with both emotional stability ($r = .193$, $p < .011$) and openness to new experiences ($r = .211$, $p < .005$,
- agreeableness demonstrated a negative, low-intensity, and significant correlation with the power-prestige factor ($r = - .233$, $p < .002$),
- a positive, medium-strength, and significant association ($r = .351$, $p < .001$) was identified between extraversion and openness to new experiences,
- a positive, medium-strength, and significant correlation between conscientiousness and openness to new experiences ($r = .300$, $p < .001$),
- the conscientiousness variable was

positively correlated, with medium intensity and significance, with the retention-time variable, r = .352, p < .001, and had a positive, low-intensity, and significant correlation with the emotional stability variable (r = .206, p < .007),

- a negative correlation of low intensity and significance was obtained between the emotional stability variable and the distrust variable (r = -.299, p < .001),
- a negative correlation of medium intensity and significance was obtained between emotional stability and the anxiety variable (r = - .289, p < .001),
- openness to experience correlates positively, significantly, and with low intensity with the retention-time dimension (r = .179, p < .019),
- the retention-time dimension correlates positively, significantly, and with low intensity with the conscientiousness variable (r = .194, p < .011) and the emotional stability variable (r = .161, p < .035),
- the distrust dimension correlates negatively, with medium intensity and significance with the emotional stability factor (r = -.299, p < .001) and positively with low intensity and significance with the anxiety factor (r = .210, p < .006) (tab. I).

TABLE I.

Correlation analysis

Scale	M(SD[1])	2	3	4	5	6	7	8	9
Extraversion	16.15 (2.91)	0.283**	0.159*	0.153*	0.351**			-0.177*	
Agreeableness	19.19 (1.26)		0.166*	0.193*	0.211**	0.233**			-0.159*
Conscientiousness	17.23 (2.40)			0.206**	0.300**		0.194*		
Emotional stability	16.47 (2.96)						0.161*	-0.299**	-0.289**

Anxiety	7.97 (1.77)					0.348**		0.210**	

[1] Means and Standard deviation (M±) and correlation analysis data

* Correlation is significant at the 0.05 level (2-tailed)/**Correlation is significant at the 0.01 level (2-tailed)

The hypotheses were tested using a stepwise multiple regression analysis. The predictors extraversion, conscientiousness, and openness to new experiences explain 8.1% of the variance in the retention-time variable (F(1.132) = 5.43, p < .021) (fig. 1).

Extraversion and emotional stability accounted for 8.5% of the variance in the distrust dimension measured by the questionnaire on teachers' attitudes toward money (F(1.133) = 11.35, p < .001).

This result suggests that high levels of

extraversion and good emotional stability may contribute to reducing distrust, as individuals who are more open and emotionally balanced may perceive social relationships and professional interactions in a more positive way. Certain personality traits appear to be associated with lower vulnerability to financial anxiety and distrust, suggesting a potential buffering effect (fig. 2).

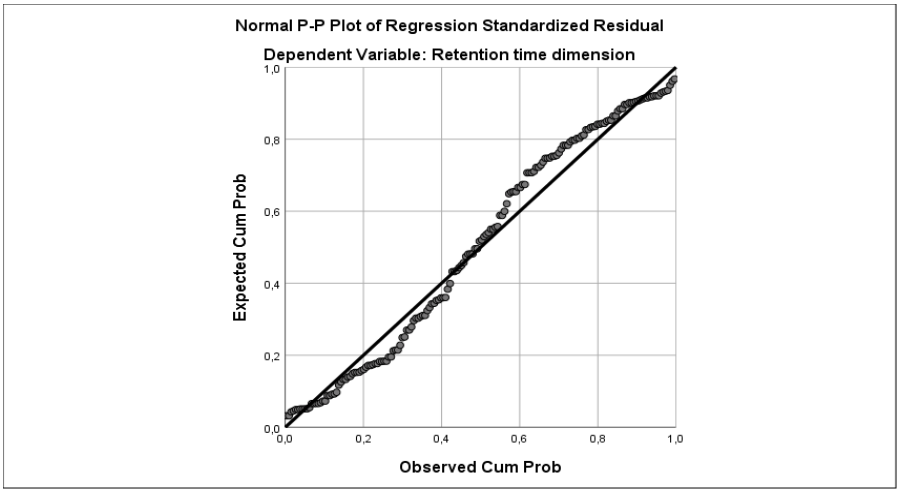

Fig. 1. Graphical representation of regression for the retention-time variable

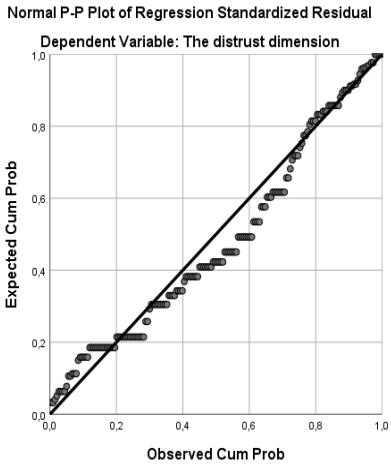

Fig. 2. Graphical representation of regression for the variable distrust

The emotional stability predictor explained 8.6% of the variance in the anxiety variable ($F(1.133) = 10.52$, $p < .001$). The results highlight that the level of emotional stability has a protective role against financial anxiety. Teachers with low emotional stability tend to perceive money-related situations as threatening and stressful,

which amplifies psychological tension and concerns about financial security. In contrast, emotionally balanced individuals are better able to regulate their affective responses and reduce the tendency to view money as a source of anxiety (fig. 3).

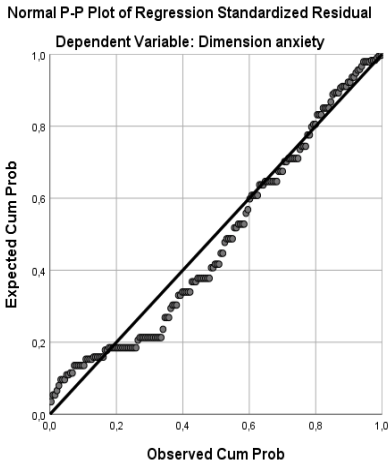

Fig. 3. Graphical representation of regression for variable anxiety

The predictors emotional stability and gender of the subjects explain 14.6% of the variance in the power-prestige variable ($F(1.133) = 18.21$, $p < .001$). The findings show that both emotional stability and gender influence the perception of money as a symbol of status and power. Male teachers, particularly those with a high level of emotional stability, tend to associate money with social prestige and personal success. This attitude reflects the use of financial resources as a way of affirmation and influence in social and professional contexts. (fig. 4).

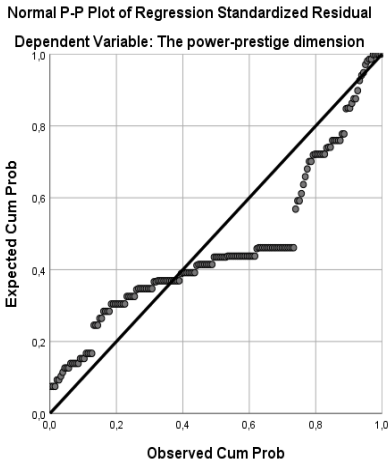

Fig. 4. Graphical representation of regression for power-prestige variable

The application of univariate ANOVA analysis revealed a significant interaction effect between the level of emotional stability and the level of conscientiousness of teachers on the trust dimension (F(1.168) = 2.73, p = .049). Specifically, teachers exhibiting both low conscientiousness and low emotional stability (M = 9.52 ± 1.69) demonstrated a significantly higher degree of distrust (t(108) = 3.13, p < .002), compared their counterparts with low conscientiousness but high emotional stability (M = 8.41 ± 1.91).

These results show that low levels of conscientiousness, combined with fragile emotional stability increase the risk of distrust. Teachers who are less organized and more emotionally vulnerable may be more likely to perceive the financial and professional environment as unpredictable or threatening. Conversely, elevated emotional stability appears to mitigate distrust even when conscientiousness is low, emphasizing the role of emotional regulation mechanisms (fig. 5).

An interaction effect was observed between the independent variables of gender and age of the subjects on the emotional stability factor, F(1.165) = 3.77, p = .025). Detailed results are presented in *Fig. 6*. Specifically, male teachers aged 19-39 (M = 17.11 ± 2.63) exhibited significantly higher levels of emotional stability t(60) = 2.74, p < .010), compared to their female counterparts in the same age group (M = 15.09 ± 2.62).

These results suggest that both gender and age influence contribute to differences in emotional stability among teachers. Young male teachers may demonstrate greater emotional resilience when encountering professional challenges, whereas women within the same age group experienced heightened pressures related to personal and professional responsibilities. (fig. 6).

An interaction effect was identified between the independent variables of gender and age of the subjects on the retention-time dimension, F(1.165) = 3.39, p = .036) (fig. 7).

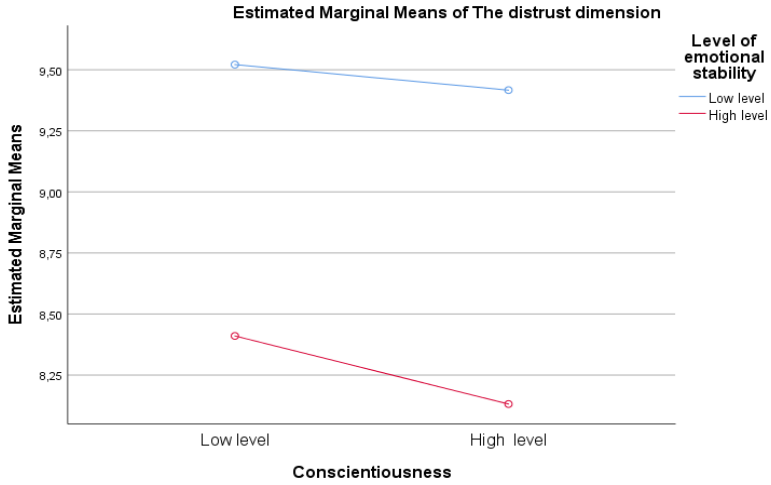

Fig. 5. Graphical representation of the interaction effect between emotional stability and conscientiousness on the dimension of distrust

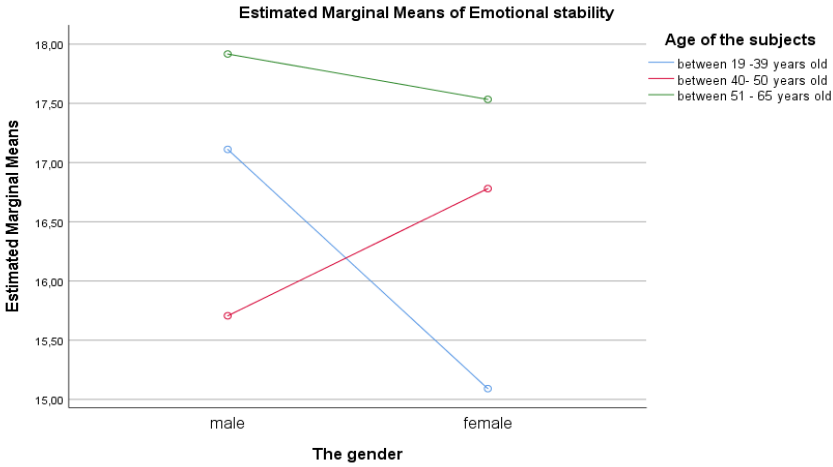

Fig. 6. Graphical representation of the interaction effect between subject gender and subject age on the emotional stability factor

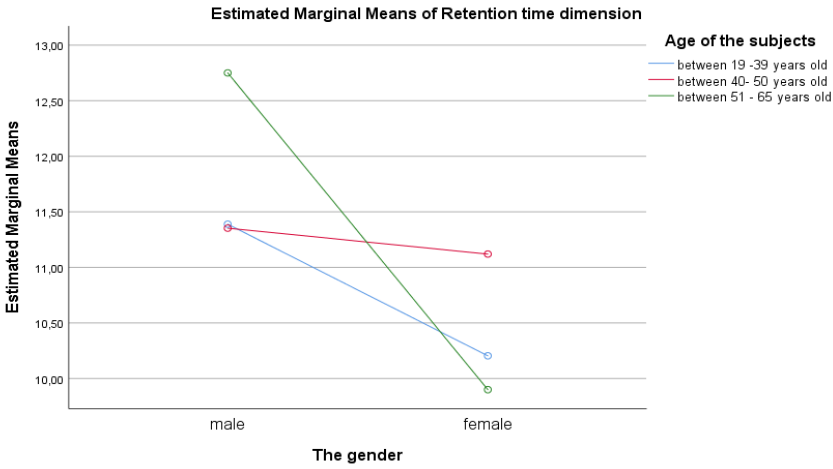

Fig. 7. Graphical representation of the interaction effect between subject gender and subject age on retention-time

Female teachers aged 51 to 65 years (M = 9.90 ± 2.21) exhibited significantly lower level of retention-time ($t(40) = 3.99$, $p < .000$), compared to their male counterparts in the same age group (M = 12.75 ± 1.71).

These results suggest that the aging process, combined with gender differences, may influence cognitive performance. Women in the final stage of their teaching careers appeared to be more vulnerable to a decline in retention-time, possibly due to biological and psychosocial factors, while male teachers in the same age group maintained their cognitive functioning for a longer period (fig. 7).

An interaction effect was identified on

the power-prestige dimension for the independent variables gender and age of the subjects F(1.165) = 3.78, p = .025 (fig. 8).

Thus, teachers aged between 40 and 50 who were male (M = 9.17 ± 1.28) exhibited a significantly higher level of power-prestige t(65) = 3.54, p < .001 than female teachers in the same age group (M = 8.34 ± 0.62).

The power-prestige dimension refers to the perception of money as a symbol and instrument of power, used to impress and influence others, functioning also as an indicator of success, social status, and prestige. Male participants in this age range were more likely to associate financial behavior with status acquisition, whereas female participants tended to show greater interest in the products themselves.

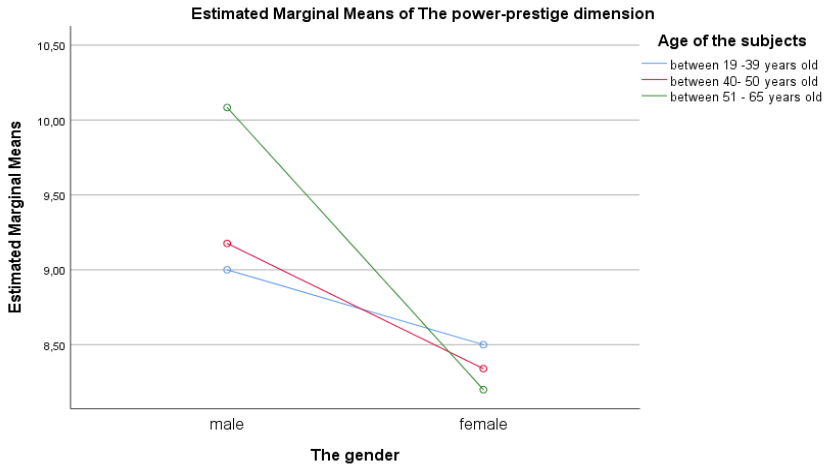

Fig. 8. Graphical representation of the interaction effect between gender and age on power-prestige

Applying the t-test for independent samples revealed significant differences between female and male teachers in terms of agreeableness (M = 19.31 ± 1.06), with results indicating that female teachers scored higher than male teachers in this trait (t(169) = - 2.16, p < .032). Male teachers showed significantly higher scores in the power prestige factor (M = 9.34 ± 1.95, t(169) = 4.85, p < .000) and the retention-time factor (M = 10.50 ± 2.36, t(169) = 3.20, p < .002) compared to female teachers. Previous studies have suggested that, in mid-career stages, men may show stronger status-driven financial orientations, associating financial resources with professional recognition and autonomy (27, 28).

These findings indicate that women exhibited higher levels of agreeableness than men - a trait associated with cooperation, empathy, and effective management of relationships and conflicts in the school environment. From a psychosocial perspective, the difference may reflect both gender socialization patterns and relationship-oriented professional roles (e.g., interacting with students and collaborating with families). Differences in perceived prestige and retention-time should be interpreted in terms of age, seniority, and teaching loads, as these factors may mediate or moderate

the link between agreeableness and professional outcomes.

Statistical analysis of the age variable revealed significant differences in emotional stability among teachers. Specifically, those aged between 40 and 50 years demonstrated a significantly higher level of emotional stability compared to their colleagues aged 19-39 ($M = 16.41 \pm 2.82$, $t(127) = -2.30$, $p < .023$). Similarly, teachers aged 51-65 exhibited a greater degree of emotional stability compared to those aged 19 to 39 ($M = 17.58 \pm 2.80$, $t(103) = -3.45$, $p < .001$). These differences suggest that accumulated professional experience and psychological maturation may contribute to enhanced emotional stability in older teachers. Mid-career teachers have developed more effective strategies for managing stress and adapting to the demands of the profession, while younger teachers are still in the process of developing these mechanisms.

Teachers aged between 19 and 39 showed a significantly higher level of distrust compared to their colleagues aged between 50 and 65 ($M = 9.35 \pm 1.89$, $t(103) = 3.15$, $p < .002$). This result suggests that distrust is more pronounced among young teachers, possibly due to financial instability and lack of professional experience. Conversely, older teachers, who typically possess more established careers and greater economic security, tend to perceive external threats less intensely, resulting in lower levels of distrust.

DISCUSSION

The present study investigated the associations between the Big Five personality traits and money attitudes among Romanian schoolteachers. Overall, the results partially supported the proposed hypotheses, indicating that personality traits influence the way teachers cognitively and emotionally relate to money. Although the effect sizes were modest, these findings align with prior research emphasizing that personality exerts subtle yet consistent effects on financial cognition and behavior (29, 30, 31, 32).

Consistent with previous literature, emotional stability was statistically associated with lower levels of financial distrust and anxiety. This pattern suggests a potential buffering relationship between emotional stability and money-related stress, rather than a direct or causal effect. Teachers with higher emotional stability were less likely to experience worry or insecurity regarding financial matters, suggesting that effective emotional regulation may buffer against money-related stress. Similarly, the combination of low conscientiousness and low emotional stability predicted greater financial distrust, supporting the notion that self-discipline and emotional resilience jointly contribute to confidence in financial decision-making. These results extend earlier studies showing that neuroticism and impulsivity are linked to financial anxiety and poorer financial management (12, 15, 33). Similar patterns linking financial stress to anxiety, depression, and burnout among teachers have been reported in recent large-scale studies conducted in different cultural contexts, highlighting the global relevance of financial well-being as a component of occupational mental health (34, 35).

Regarding the retention-time dimension, extraversion, conscientiousness, and openness to experience were positive predictors. Teachers who were more sociable, organized, and intellectually curious tended to plan ahead and adopt a future-oriented

financial perspective. This finding is consistent with previous evidence linking conscientiousness and openness to financial prudence and long-term goal setting (36-38)

In contrast, the power-prestige dimension was influenced by both emotional stability and gender, indicating that male teachers with higher emotional stability were more likely to associate money with status and social recognition. Similar gender-based distinctions in financial attitudes have been reported in other studies, where men perceive money as an indicator of achievement, while women exhibit greater relational and emotional orientations toward spending (39, 40). It should be noted that the gender-related findings should be interpreted cautiously. The sample was unbalanced, with a higher proportion of female participants, which may have influenced the observed mean differences. Moreover, socio-cultural norms regarding gender roles and financial behavior in the Romanian context could partly explain these results, rather than reflecting intrinsic personality-based distinctions. This result aligns with prior studies suggesting that men in mid-career stages tend to associate financial success with professional recognition and autonomy. Such attitudes may reflect culturally reinforced norms linking financial resources with social achievement and status, especially among individuals with stable employment and family responsibilities

Age-related analyses revealed that older teachers displayed higher emotional stability and lower financial distrust, suggesting that professional experience and psychological maturity contribute to greater financial confidence. Younger teachers, facing early-career instability and lower financial security, tended to experience higher anxiety and distrust-patterns observed across various populations (41, 42, 43, 44). These results highlight the interplay between demographic factors and personality in shaping financial perceptions, which may have implications for teacher support and retention programs.

From a psychological and occupational health perspective, the findings underscore the importance of addressing financial well-being as part of comprehensive mental health initiatives for educators. Personality-informed interventions - such as financial coaching integrated with emotional regulation training - could help teachers develop healthier attitudes toward money, thereby reducing stress and improving well-being . Incorporating such programs within school health policies may contribute to mitigating burnout and enhancing job satisfaction. In line with personality-based financial models, individual differences in Big Five traits have also been shown to relate to long-term financial outcomes and perceived financial success, supporting the relevance of personality-informed approaches to financial well-being interventions (45, 46, 47, 48).

Strengths and limitations. This study fills a gap in the literature by examining the intersection of personality and financial attitudes in a professional group often neglected in financial psychology research. The use of validated instruments (Big Five© plus-short, MAS) and inclusion of both personality and sociodemographic variables strengthen the findings. However, the study's cross-sectional design limits causal inference, and the sample - composed of teachers from a single Romanian region - reduces generalizability. The reliance on self-reported data may also introduce response biases. Future studies should

replicate these findings using larger and more diverse samples, and consider longitudinal or experimental designs to explore causal mechanisms.

Health Policy and Practical Implications. At the institutional level, financial well-being should be recognized as an integral component of teachers' occupational health. Educational and health authorities could integrate financial literacy and psychological resilience training into teacher development programs. Early identification of individuals with high financial anxiety or distrust could guide targeted interventions to prevent stress-related outcomes. Embedding such measures in school health frameworks aligns with *Health Care*'s focus on mental well-being and sustainable workforce health.

Personality traits - particularly emotional stability, conscientiousness, and extraversion - play a modest but meaningful role in shaping teachers' financial attitudes. Understanding these psychological underpinnings offers valuable insights for developing financial awareness and mental health support programs tailored to educators. Promoting financial confidence and emotional balance may indirectly enhance teachers' occupational functioning, job satisfaction, and overall well-being.

CONCLUSIONS

The study demonstrates that personality traits play a protective role in how teachers relate to financial confidence and trust.

Teachers who are less organized and more emotionally vulnerable may perceive the financial and professional environment as unpredictable or threatening. Women showed higher levels of agreeableness than men - a trait associated with cooperation, empathy, and effective management of relationships and conflicts in the school environment.

Moreover, professional experience and psychological maturity appear to contribute to greater emotional stability, suggesting that early-career support and mentoring could help novice teachers adapt more effectively to workplace demands.

Although the observed correlations were modest, they are consistent with previous evidence indicating that personality-related effects on financial cognition are subtle but meaningful over time. From a practical standpoint, these findings suggest that financial awareness and well-being programs for teachers should incorporate personality-informed approaches. Interventions aimed at reducing financial anxiety could include emotional regulation strategies for individuals with lower emotional stability, whereas financial planning workshops might focus on enhancing retention - time attitudes among teachers with lower conscientiousness.

At a broader level, educational policymakers and school management structures may consider integrating light psychological screening for financial attitudes as part of teacher support and mentoring initiatives. Such measures would not serve diagnostic purposes but could guide preventive and supportive actions, helping teachers develop healthier cognitive and emotional relationships with money-ultimately contributing to occupational well-being, mental health, and long-term retention in the profession.

LIFE QUALITY IMPROVEMENT IN PATIENTS WITH ORAL SQUAMOUS CELL CARCINOMAS USING TOTAL DENTURES(Abstract**) Aim:** Treatment of oral cancer patients is followed by the occurrence of significant functional and aesthetic alterations. Dental rehabilitation is the key factor for post-op life quality. **Material and methods:** The study included 22 patients treated for squamous cell carcinoma: tongue (11 cases), floor of mouth (10 cases) and lower lip (1 case). The study group included only edentulous patients with appropriate mandibular bone height. The group was further divided into three subgroups: patients requiring floor-of-mouth lowering (9 cases), patients who needed lower labial vestibuloplasty (8 cases) and patients who required a vestibule and a floor-of-mouth extension procedure (5 cases). Healing was by second intention in most patients by using an acrylic splint fixed by circummandibular wire and maintained in place 4 weeks (16 cases). Eight patients underwent vestibuloplasty: in 3 using total skin grafts, 3 - jugular mucosa and in 2 cases palate mucosa. The acrylic splint was made for two patients out of eight. **Results:** Secondary tissue retraction did not allow the proper retention of the mandibular removable prostheses in 3 patients who delayed their appointments. Prosthesis was made without any inconvenience in all other patients. Thereby 19 out of 22 patients had significant improvement in all functional aspects (mastication and swallowing), as well as facial aesthetics (restoring the vertical dimension of the lower face). **Conclusions**: Using less traumatic and non-expensive surgical techniques, quality of life patients with oral SCC can be greatly increased, allowing the social reintegration of these individuals. **Keywords:** ORAL CANCER, MANDIBULECTOMY, GLOSECTOMY, VESTIBULOPLASTY, PREPROSTHETIC SURGERY.

The sixth most common cancer is the oral and oropharyngeal cancer and in 90 % of the cases the squamous cell carcinoma (SCC) is involved with or without the presence of the metastasis in the cervical lymph nodes. The most frequent localizations are the tongue and the floor of the mouth (fig. 1).

The literature showed that the incidence of the oral cancer is in direct relationship with the chronic use of alcohol and/or tobacco. The treatment of choice for this type of oral cancer is radical primary surgery, with reconstruction by free tissue transfer where indicated (1, 2, 3).

Oral cancer treatment can affect secondary the quality of the patient's life by producing complications such as disfig-

urement, impaired speech, masticatory dysfunction, dysphagia, or dysarthria. The dysfunctionalities that occur after the oral cancer resection have a significant impact on the patients' lives. Some experience difficulties in eating and speaking (4, 5) others can remain with psychosocial sequelae that can change the relationship and the acceptance of the society making the head and neck cancer patients distressed (6).

Fig. 1. SCC left floor of mouth

To obtain a quality life as high as possible for a head and neck cancer patient we must find a way to rehabilitate the postsurgical defect from dental point of view. Rehabilitation of mandibular defects associated with tumor resection present a significant challenge for prosthodontic rehabilitation (7). Reestablishing occlusion and optimizing tongue mobility are important to post-operative oral function (8). There are many cases where periprosthetic surgery is needed, to obtain a stable prosthetic field (fig. 2).

This study concentrates on the possibilities for dental rehabilitation of oral cancer treated patients.

Fig. 2 Post-op intraoral aspect after treatment of carcinoma by direct suture, with the disappearance of the paramandibular trench

MATERIAL AND METHODS

A total of 22 patients admitted to the Oral and Maxillofacial Surgery Clinic of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital were recruited after at least one relapse-free year post surgery. The subjects underwent a glossopelvectomy, associated or not with marginal mandibulectomy; in one patient was performed a lower lip resection in the study hospital between January 2013 and August 2017. All patients were males, aged 47 to 72 years at the time of surgery. Eleven patients (50%) were diagnosed with tongue cancer, 6 (27.2%) with cancer of the lateral floor of the mouth, 4 (18.1%) with cancer of the anterior floor of the mouth and 1 patient (4.5%) with lower lip cancer. The reconstruction techniques used at the primary surgery were: direct suture 13 cases (59%), cicatrization / healing *"per secundam"* 4 cases (18.18%), free split-thickness skin grafts 2 cases (9%), radial forearm free flap 2 cases (9%), and Camille Bernard technique for lower lip reconstruction 1 case (4.5%).

The study group containing only edentulous patients was further divided into three subgroups: (1) patients who needed floor-of-mouth lowering (9 cases), (2) patients who needed lower labial vestibuloplasty (8 cases) and (3) patients who needed vestibule and floor-of-mouth extension procedure (5 cases). In all patients included in the study, the orthopantomography highlighted appropriate mandibular crest height for total denture restauration.

Floor-of-mouth lowering technique. The technique used in lowering the floor of the mouth involved detaching the mylohyoid muscles from the mylohyoid ridge area and repositioning the muscle inferiorly, (effectively deepening the floor of the mouth area) and relieving the influence of the mylohyoid muscle on the alveolar crest. After the intervention, we applied an occlusal splint secured to the mandible with circummandibular wires for 4 weeks. Healing was by second intention (fig. 3).

Fig. 3 Post-op lowering floor of mouth

Vestibuloplasty technique. Vestibuloplasty technique implied the deepening of the vestibule by lowering the connection of the mucosa and muscle. In this study, we used three techniques: (1) skin graft technique, (2) mucosal graft technique (jugal and palatal mucosa), and (3) dental split technique with healing by second intention.

Full-thickness grafts were used over the denuded area after the apical extension of the vestibule in 3 cases (13.63%) (including a patient with vestibule and floor-of-mouth extension procedure). The skin donor site was obtained from the supraclavicular area. Fixation of the graft was performed by surgical sutures.

We used two types of mucosal grafts: jugal mucosal grafts in 3 cases (13.63%) (including a patient with vestibule and floor-of-mouth extension procedure) and palatal mucosal grafts in 2 cases (9%).

Vestibuloplasty using dental split technique with healing by second intention was performed in 2 patients (9%).

Vestibule and floor-of-mouth extension technique. This technique implied a simultaneous procedure for the deepening the vestibule and lowering the floor of the mouth, where the denuded area remained uncovered. Healing was by second intention, using a dental split secured to the mandible with circummandibular wires for 4 weeks (fig. 4).

Fig. 4. Splint. After the deepening of the paramandibular shafts, an acrylic collar was used to protect the postoperative wound and to guide the secondary scarring

RESULTS

Initially, in all patients we obtained a good depth of the paramandibular trenches. Three of the patients (13.63%) in whom we used the *"per secundam"* healing technique, did not show up to their appointment to have the dentures made. The first surgical outcome was lost, and the prostheses did not have adequate stability. None of these patients ever wanted a corrective secondary intervention. In the remaining patients the prosthetic dressing was performed without any difficulties, 11 patients (50%) of whom were entrusted to dental practitioners.

In all patients in whom dentures were made, the functional results were excellent increasing the quality of mastication and swallowing (fig. 5).

Fig. 5. Dentures in a post-op lowering floor of mouth patient

Restoring lower facial height contributed to the improvement of facial aesthetics (fig. 6).

Fig. 6. Post-op view (front and profile) with dentures

DISCUSSION

After oral cancer surgery, tissue defects can cause deformity, limited mobility, complicating many essential functions and leading to a decreased quality of life (5). The prosthetic treatment in oral cancer

treated patients can be difficult and challenging, but it is an important step in improving the quality of life. In our study, at the extraoral examination, all patients presented with decrease of the lower facial third in relation to the middle third and the accentuation of the natural folds (fig. 7).

The main prosthetic problems consist in the loss of movable mucosa in the buccal and lingual part, changes in jaw direction toward the affected side and the loss of the masticatory mucosa (5). The aim of the preprosthetic surgery of the mandible is to increase the stability of the prosthesis (9, 10) fact that can be achieved by deepening the sulcus on the buccal/lingual side or on both (buccal and lingual) sides of the mandible.

Fig. 7. Post-op view (front and profile) without dentures

The principle of vestibuloplasty is that the vestibulum is extended apically by surgically shifting the tissue apically and the denuded open exposed soft tissue area is left for secondary epithelization. The thought behind this is that the denture-bearing area can be extended. However, the extension of the vestibulum results in rapid relapse due to scar contraction. To avoid this, attempts have been made to cover the denuded area by a graft (11). Free grafts can be classified into skin grafts and mucosal grafts (palatal mucosa, buccal mucosa).

Skin grafts have been used as good alternatives since they encounter no problems with shrinkage and scars, which are unavoidable in the secondary epithelialization process. Studies show a high level of satisfaction in patients with vestibuloplasty with partial thickness skin graft. When used in the mouth, skin has associated problems that lead to patient dissatisfaction: it is a different color and texture from normal mouth epithelium; in the first years after grafting, there is a bad taste or odor, probably resulting from the presence of

hair and sebaceous glands in the graft and insufficient oral hygiene; and the development of scars and discomfort in the donor site (10).

Palatal tissue offers the potential advantages of providing a firm, resilient tissue, with minimal contraction of the grafted area. Although palatal tissue is relatively easy to obtain at the time of surgery, the limited amount of tissue and the discomfort associated with donor site harvesting are the primary drawbacks. In areas where only a small localized graft is required, palatal tissue is usually adequate (12).

Full-thickness jugal mucosa harvested from the inner aspect of the cheek provides advantages like those of palatal tissue. This mucosa does not become keratinized, and often results in an inadequate denture-bearing surface in case of inadequate technique of suturing at the periostea (12).

The combination procedure of vestibule and floor-of-mouth extension technique effectively eliminated the dislodging forces of the mucosa and muscle attachments and provides a broad base of fixed keratinized tissue on the primary denture-bearing area.

The prosthetic field we obtained was very easy to dent even by the dentists who are not familiar to difficult scar tissue situations. Using less traumatic and non-expensive surgical techniques it is possible to have a nice prosthetic field. This field is then easily covered with total dentures thereby improving all functionally aspects (mastication, deglutition, speech and language). At the same time the, restoring the lower face vertical dimension, the facial aesthetic was improved.

Improving quality of life may be as important as eradicating the cancer and should be identified as a final treatment goal. Studies showed that even if oral function was not restored sufficiently, oral health-related quality of life improved with the placement of a maxillofacial prosthesis (5).

CONCLUSIONS

In our study we used less traumatic and non-expensive surgical techniques. The life quality of patients with oral SCC can be greatly increased using these techniques. Restoring occlusion with removable prosthesis, extraoral aspect and all the functions as mastication, phonation and phonation are improved. So, this allows the social reintegration of these individuals.

NEWS

NEW FINDINGS ON HUMAN PAPILLOMA VIRUS VACCINATION

Human papilloma virus (HPV) is an oncogenic virus, 13 of the 100 types being responsible for cancer of various sites: cervix, vulva, vagina, anus, penis, tonsils, and base of the tongue. Cervical cancer is the fourth most common cancer in women worldwide and is most commonly caused by HPV types 16 and 18. According to the World Health Organization, 58 countries have introduced anti-HPV vaccination into national immunization programs. Two vaccines containing purified viral proteins for HPV are currently available: the bivalent vaccine (types 16 and 18) and the quadrivalent vaccine (types 6, 11, 16 and 18). A recent study conducted by Huh WK and collaborators evaluated the efficacy of a new ninevalent vaccine that includes the types HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58. The study group included 14 215 participants of whom 7106 were vaccinated with ninevalent vaccine and 7109 were immunized with quadrivalent vaccine. The results showed that the ninevalent vaccine had more than 97% efficacy against types 31, 33, 45, 52, and 58. Both vaccines have demonstrated similar efficacy against types 6, 11, 16 and 18. These results support the inclusion of the ninevalent vaccine in national immunization programs. This measure could increase to 90% prevention in cervical cancer (Huh WK, Joura EA, Giuliano AR, Iversen OE, de Andrade RP, Ault KA, Bartholomew D, Cestero RM, Fedrizzi EN, Hirschberg AL, Mayrand MH, Ruiz-Sternberg AM, Stapleton JT, Wiley DJ, Ferenczy A, Kurman R, Ronnett BM, Stoler MH, Cuzick J, Garland SM, Kjaer SK, Bautista OM, Haupt R, Moeller E, Ritter M, Roberts CC, Shields C, Luxembourg A. Final efficacy, immunogenicity, and safety analyses of a nine-valent human papillomavirus vaccine in women aged 16-26 years: a randomised, double-blind trial. *Lancet*. 2017 Sep 5. pii: S0140-6736(17)31821-4. doi: 10.1016/S0140-6736(17)31821-4. USING OF MULTIPLE CHROMOSOMAL AND MOLECULAR ANALYSES TO ELUCIDATE THE ETIOLOGY OF PLURIMALFORMATIVE SYNDROMES (Abstract): Congenital anomalies are structural or functional abnormalities occurring during intrauterine life in 3% of all pregnancies, representing an important public health problem through frequency, morbidity and mortality. In 6% of cases they are determined by unbalanced chromosomal abnormalities and their cytogenetic diagnosis is a prerequisite for proper management including proper genetic counseling. **Material and methods**: The retrospective study included 331 patients who were investigated by clinical and cytogenetic (conventional or molecular) methods at the Genetics Pathology Center in Iaşi, from 1 January 2015 to 31 December 2016. **Results**: The study group was divided into four subgroups: patients with plurimalformative syndromes or patients with association of multiple congenital anomalies (108 cases of which in 25 patients were confirmed with an unbalanced structural or numerical chromosomal abnormalities), patients with craniofacial dysmorphism (88 cases - in five cases cytogenetic abnormalities were confirmed), patients with Down syndrome (96 cases - 90 being cytogenetically confirmed), patients with Turner syndrome (39 cases of which 16 were cytogenetically confirmed). In 24 patients Fluorescence in Situ Hybridization (FISH) was applied with probes for the chromosomal regions involved in clinically suspected microdeletion syndromes and in 12 cases these were confirmed. In the other 12 cases (not confirmed by karyotype / FISH) we demonstrated that the syndrome is generated by another type of molecular mechanism using Multiplex ligation dependent probes amplification (MLPA). In 11 cases with complex chromosomal abnormalities, the investigation continued and the array CGH investigation is still in progress. **Conclusions**: Elucidation of the chromosomal etiology of congenital anomalies is important for providing appropriate genetic counseling and identifying other people with high genetic risk in their family. **Keywords**: CONGENITAL ANOMALIES, UNBALANCED CHROMOSOMAL ANOMALIES, KARYOTYPE, FLUORESCENCE IN SITU HYBRIDIZATION, MICRODELETION SYNDROME.

Congenital anomalies (CA) are structural or functional abnormalities that occur during intrauterine life and can be identified prenatally, at birth or later in life (1).

They affect about 3% of all pregnancies and 10-20% of cases are identifiable syndromes (2). Etiology is heterogeneous: 45% have genetic causes, 5% non-genetic and, in approximately 50% of cases, a causal factor cannot be established (3, 4). Among the genetic causes we mention: unbalanced chromosomal abnormalities (6% of total CA), monogenic mutations (7.5% of isolated CA), multifactorial hereditary diseases (20-30%) (5).

CA are a major public health problem because they are frequent and severe birth defects, representing an important cause of intrauterine death and infant morbidity and mortality (6,7). The EUROCAT Statistical Monitoring Report-2012, which aimed at pan-European analysis of births from the period 2003-2012, revealed that there is an ascending trend for chromosomal abnormalities due to the increase in the prevalence of Down and Edwards syndrome determined by the increase in maternal age in Europe (8).

For the detection of unbalanced chromosomal abnormalities involved in CA pathogenesis, chromosomal analysis is required. The cytogenetic techniques used are *conventional cytogenetic techniques* (karyotype) and *molecular cytogenetic techniques* (FISH, M-FISH, MLPA, QF-PCR, CGH, DNA microarrays). Depending on the number of abnormalities identified, there are pangenomic and targeted techniques.

Pangenomic techniques (karyotype, M-FISH, DNA microarrays) can reveal several anomalies that may be of interest to all chromosomes. Target techniques (FISH) can reveal fewer anomalies that only interest certain chromosomes.

MATERIAL AND METHODS

Our study was based on conventional banding cytogenetic, FISH analyses and MLPA. In all cases, the chromosomal analysis was performed on a short time T lymphocyte culture stimulated by phytohemagglutinin. The chromosomes were G-banded using trypsin and Giemsa solution according to standard techniques. The FISH and MLPA methods were applied only in selected cases when a microdeletion syndrome was suspected. The results of conventional banding cytogenetic analysis and FISH were elaborated in accordance with the guidelines of the International System of Human Cytogenetic Nomenclature (ISCN) (2013) (9).

The study group consisted of 331 patients clinically investigated at the Genetics Pathology Center in Iaşi. Conventional and molecular cytogenetic diagnostic investigations were applied in the Cytogenetics Laboratory of the University of Medicine and Pharmacy "Grigore" T. Popa "Iasi, from 1 January 2015 to 31 December 2016.

The study group was subdivided into four subgroups depending on clinical suspicion:

- Subgroup A. Patients with plurimalformative syndromes or with association of multiple congenital anomalies
- Subgroup B: Patients with craniofacial dysmorphism
- Subgroup C. Patients with clinical suspicion of Down syndrome
- Subgroup D. Patients with clinical suspicion of Turner Syndrome

RESULTS

The four subgroups had the following composition:

- Subgroup A –108 cases, of which 54 males and 54 females;
- Subgroup B - 88 cases, of which 32 males and 56 females;
- Subgroup C - 96 cases, of which 40 males and 56 females;
- Subgroup D - 39 cases.

Investigations of the patients from subgroup A (pluriformative syndromes) and subgroup B (craniofacial dysmorphism) by conventional chromosomal analysis - G-banded karyotype – confirmed the presence of unbalanced numerical or structural chromosomal abnormalities in 28 cases (table I).

In other 24 patients from the subgroup A or B, the clinical phenotype was suggestive for a plurimalformative syndrome generated by a chromosomal microdeletion: Williams syndrome, Wolf-Hirschhorn syndrome, velocardiofacial syndrome, Prader-Willi syndrome, Angelman syndrome, *cri du chat* syndrome, Miller-Dicker syndrome. In these cases, we applied FISH method using appropriate DNA probes from Metasystem®, Cytocell® and Kreatech®:

- For Williams syndrome, there was only one case confirmed by the FISH method using specific 7q11.23 probes.
- Wolf-Hirschhorn syndrome clinical suspicion was in seven cases; four of these were not confirmed by FISH method, using specific 4p16.3 probes and neither by MLPA; in other 3 cases, the FISH and MLPA confirmed the presence of 4p16.3 microdeletion.
- In the case of velocardiofacial syndrome, there were seven cases, four of which were confirmed by the FISH method using specific 22q11.2 probes.
- For Prader-Willi Syndrome there were four cases, one with a 15q11-13 deletion detected on karyotype and confirmed by the FISH method, using 15q11-13 probes, one with 15q11-13 microdeletion not detected on karyotype, but confirmed by the FISH method, using 15q11-13 probes and one without cytogenetic changes (neither microscopic or infra-microscopic) but with an imprinting defect in 15q11 - 13 region; the last case was infirmed both by FISH and MLPA.
- In Angelman syndrome there was only one case, not confirmed by the FISH method, using 15q11-13 probes.
- In case of *cri du chat* syndrome, there was only one case, seen on karyotype and confirmed by the FISH method, using 5p15.3 probes.
- The only case with Miller-Dieker syndrome was confirmed by FISH method using probe for 17p13.3 region
- The main data on cases with plurimalformative syndromes and craniofacial dysmorphism with unbalanced chromosomal abnormalities are presented in Table I.
- In the subgroup C we had 96 patients with clinical suspicion of Down syndrome. Six of these cases were not confirmed by karyotype (five girls and one boy). Most of the patients had free and homogeneous trisomy 21, with karyotype 47,XX,+21, in 47 of the 51 girls with Down syndrome, respectively 47,XY,+21 in 35 of the 39 boys with Down syndrome. We identified three cases of mosaic (47,XX,+21/46,XX two cases and 47,XY,+21/46,XY – one case).

PMS – plurimalformative syndrome; DS – Down syndrome; MOS – Moebius syndrome; CFD – craniofacial dysmorphism; VCFS – velocardiofacial syndrome; CCS – cri du chat syndrome; CLS – Cornelia de Lange syndrome; MS – Morris syndrome; PWS – Prader-Willi syndrome; WS – Williams syndrome; WHS – Wolf-Hirschhorn syndrome; MDS – Miller-Dieker syndrome; PS – Patau syndrome; * -father of case 284; ** - mother of case 284

We discovered two cases of Down syndrome with robertsonian translocation between chromosomes 14 and 21: 46,XY,rob(14;21)(q10;q10).

Excepting the typical chromosomal formulas, in subgroup of Down syndrome patients we found some particular karyotype: 46,XX,dic(14;22)(p11.2;p11.2),+21, 46,XY, ins(21;16) (q22.1;p12.1p13.13) and 47,XX,1qh+,16qh+,+der(21)del(21)(q11.2q 22.1).

In clinical suspicion of Turner syndrome (subgroup D), 23 cases were not confirmed and 16 cases were confirmed, with different abnormal chromosomal formulas (tab. II). In six cases, a homogenous anomaly was present: X monosomy (five cases) and a Xq isochromosome (one case). In the other ten cases, we identified different types of mosaics with two or three cell lines. In two cases we discovered aneuploid mosaics: 45,X/46,XX and 45,X/47,XXX. In other cases, we found mosaics that had an association between a complete X monosomy and a partial X monosomy produced by an unbalanced structural chromosomal anomaly (Xq isochromosome – 5 cases; X ring chromosome – 1 case; deletion on the long arm of X chromosome – 1 case; dicentric X chromosome – 1 case).

* array-CGH in progress

Of the cases where chromosomal analysis has detected abnormal chromosomal formulas we present a case to illustrate sequential genetic diagnosis.

Clinical case 83

Patient B, male, from rural area, was investigate in Medical Genetics Center at the age of 3 days due to the presence of a plurimalformative syndrome.

Birth occurred naturally, after 35 weeks of amenorrhea. Ultrasound monitoring of pregnancy in this case was not made. The child was born by a 16-year-old minor unmarried mother.

Newborn anthropometric data showed intrauterine growth retardation: weight – 2100 g; length - 44 cm; head circumference - 29 cm; APGAR score- 5.

The clinical examination revealed the existence of a plurimalformative syndrome with craniofacial dysmorphism (microcephaly, dolichocephaly, broad and flat nasal root, micrognathia, dysplastic ears) associated with abnormalities in the hallux position and shape, micropenis and atrioventricular defect (fig. 1).

Fig. 1. Patient B phenotype ♂

Due to the clinical aspect, peripheral blood was harvested and T-lymphocytes were cultured in vitro. The karyotype revealed the presence of a derivative chromosome, resulting from the union of segments from chromosomes 13 and 18 – chromosomal formula: 46,X,Yqh+,1qh+,der(18)t(13;18)(q12;p11.) (fig. 2).

To verify whether the derivative chromosome was monocentric or dicentric, a C-banding technique was applied, which established that this abnormal chromosome had a single centromere (fig. 3).

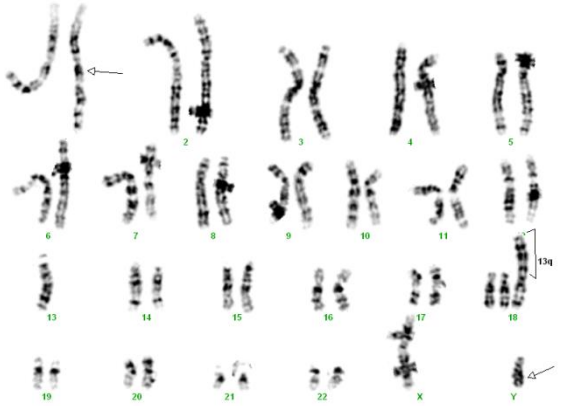

Fig. 2. G banding – karyotype 46,X,Yqh+,1qh+,der(18)t(13;18)(q12;p11.2)

Fig. 3. C banding - karyotype 46,X,Yqh+,1qh+,der(18)t(13;18)(q12;p11.2)

To identify the origin of the centromeric fragment of this chromosome, the FISH assay was performed using Metasystem® probes corresponding to chromosomes 13, 18 and 21 (commonly used for the prenatal diagnosis of aneuploidies); this analysis established that this derivative chromosome has a centromere derived from chromosome 18 (fig. 4).

To complete the investigation, the FISH test was also applied using subtelomeric probes from Cytocell® corresponding to the

long arm of chromosome 18 and the short arm of chromosome 18, which confirmed the association of a partial trisomy 13 (containing almost all the long arm of this chromosome) with a small partial monosomy (determined by the absence of the terminal end of the short arm of chromosome 18) (fig. 5).

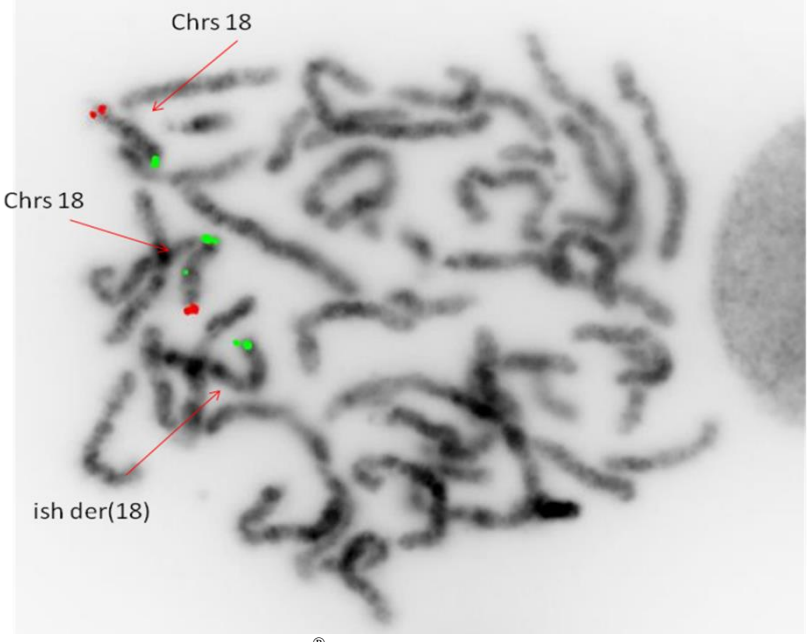

Fig. 5. FISH analysis with Cytocell® probes corresponding to the subtelomeric region of chromosome 18 red signals 18p tel – 74G18; green signals – 18q tel – dJ964M9

DISCUSSION

In our investigations of patients with congenital anomalies we used a sequential diagnostic strategy, increasing the resolution at each stage. We started with conventional karyotype (GTG banding), followed using molecular cytogenetic methods like FISH or MLPA. In cases with chromosomal anomalies to increase the precision of diagnosis we applied DNA microarrays, but definitive results are not completed.

Conventional chromosomal analysis has some disadvantages: relatively long *duration* of analysis 4-10 days; relatively limited *resolution* to 5-10 Mb; requires specialized technicians to analyze GTG banding karyotype, all these meaning high costs and organizational difficulties in small laboratories. But these types of analysis are the only genomic analysis that could identify a balanced structural chromosomal abnormality. In addition, such analysis can identify the position of a genomic imbalance in the cases with partial trisomy or partial monosomy. Thus, GTG banding karyotype continues to be a part of protocol investigation of chromosomal diseases (3, 10, 11).

In cases with a suggestive phenotype for a microdeletion syndrome / microduplication syndrome, some protocols indicate the use first of FISH or MLPA technique with locus - specific probes bound to a region of a chromosome. Even in these cases, the karyotype must be made because in some cases a derivative chromosome could be present. If the diagnosis is not confirmed by FISH or MLPA technique, the diagnostic strategy imposes a pan-genome analysis (array-CGH) able to identify subtle genomic imbalances (3, 6, 10).

Microdeletion / microduplication syndromes are produced by the loss / gain of small chromosomal fragments (1-4 Mb) impossible to be detected by conventional cytogenetic methods. The detection of such genomic imbalances requires the use of a molecular technique: FISH, MLPA or array-CGH. In a minority of cases when the chromosomal fragment involved is large, it may also be highlighted by conventional G-banded chromosome analysis. The selection of cases for the FISH test is done using clinical diagnostic scores. There must be a rigorous selection, as the analysis is expensive, laborious and targeted ("we will find only what we are looking for") (3,12).

Genomic techniques based on DNA microarrays (array-CGH) increased the resolution to 50-100 kb. The major disadvantage of this technique is the possibility of discovery of a CNV (copy number variation). The CNVs represents about 12% of the genome, and the classification in pathogen or not pathogen is difficult. If the CNV was already associated with a human disease, it is considered pathogen. If the CNV contains a high number of genes and its size is big, the CNV is considered potential pathogen. If the CNV is also present in one of the patient's parents, the CNV is benign. In the other situation when the anomaly is *de novo* and it is not associated with a specific phenotype, the CNV is considered as VOUS (variants of uncertain significance) (13-16).

Fourteen of the cases with clinical suspicion of a microdeletion syndrome were confirmed by molecular techniques (FISH and MLPA). We consider that the confirmation of approximately 60% of such cases is a proof of good clinical diagnosis. The absence of confirmation in other cases could have different explanations. In some diseases, it is present a genetic heterogeneity. In other cases, the genomic imbalance is

very small and its identification requires the use of array-CGH technique.

For example, in Wolf-Hirschhorn syndrome different types of abnormalities were described. About 55% of patients have a "pure deletion" identifiable by conventional G-banded chromosome analysis or FISH technique. In 40-45% of cases, the phenotype is the consequence of an unbalanced translocation resulting in chromosome 4p distal segment deletion. The rest of the cases were generated by complex rearrangements. (17). The FISH test detects 95% of WHS cases using a WHSCR critical region specific-probes. A false negative result can be obtained when the probe hybridizes outside of the critical region. The array-CGH technique has a good detection rate (95%) and for this reason it is recommended for the diagnosis of complex rearrangements involving the 4p16.3 critical region (18,19).

Most of cases (90-95%) with velocardiofacial syndrome present a small genomic imbalance of 22q11.2 region. For this reason, the karyotype is not useful for diagnosis. The commercial FISH probes used for the detection of abnormalities in the critical region for the velocardiofacial syndrome are TUPLE1 and N25. The FISH technique detection rate of deletions at this level is approximately 95%, the two probes being equivalent to the detection rate, but if the deletion is less than 40 kb then it cannot be highlighted. In the 22q11.2 region six duplicate segments, named from A to F, were identified. Most patients with velocardiofacial syndrome (85%) present a deletion that include the interval between segment A and D. The TUPLE1 and N25 probes are in the region between segmental duplications A and B, and for this reason the cases with other type of deletion will be not detected with 22q11.2 commercial FISH probes. In such cases, the use of array-CGH technique represents the best solution (20,21).

Prader-Willi syndrome is caused by genomic imbalances in 15q11-q13 region. Molecular classes of PWS are the following: Ia (deletion of 5-6 Mb, 65-75%), Ib (chromosomal rearrangements, <1%), II a (maternal 15q11-q13 UPD, 20-30%), IIb (maternal UPD with predisposition to parental translocation/chromosome marker, <1%), III a (imprinting defect with imprinting center deletion), III b (epimutation: imprinting defect without imprinting center deletion). Approximately 70% of individuals with PWS have a deletion involving the 15q11-q13 region, so that the proportion of cases detected by FISH method is 65-75%. If the deletions are small or atypical the FISH test result may be false negative. A very good detection rate (99%) has MLPA because it can detect both microdeletions and methylation status (uniparental disomy and imprinting defect). In approximately 1% of cases, both FISH and MLPA methods do not confirm the clinical suspicion of Prader-Willi syndrome, and the identification of genomic abnormality requires the application of array-CGH technique (22, 23).

Trisomy 21 being the most common chromosomal disease (1/650 - 1/800 newborns), requires epidemiological surveillance mainly through three types of actions: monitoring the impact of intellectual disability, screening programs evaluation and adapting medical services to associated comorbidities (24-27).

The results of chromosomal analysis in subgroup of Down syndrome are concordant with other studies. Thus, most of cases (92-95%) present a free homogenous trisomy 21. The rest of cases have a mosaic

trisomy 21 or a trisomy 21 due to a Robertsonian translocation. In the last case, the most frequent translocation is rob (14q;21q), that is concordant with our data. In less than 0,1% of cases, Down syndrome is generated by a partial trisomy 21q, chromosomal anomaly being an unbalanced reciprocal translocation, duplication, dicentric chromosome 21, marker chromosome 21 etc. (6, 24)

The clinical suspicion of Down syndrome was not confirmed in approximately 6.31% of investigated cases. This result is concordant with data previously presented by Gorduza *et al.* (2007) that indicated a 5.77% of cases with clinical suspicion of Down syndrome that are not confirmed by karyotype. A possible explanation is genetic heterogeneity, but also could be take in consideration the presence of somatic mosaicism or a mosaic trisomy 21 with a small number of abnormal cells (24, 28).

Identifying the real phenomenon could be the premises for initiating prophylactic actions. These prenatal screening and diagnosis programs are applied also in Romania, but are only partially funded by health insurance. Diagnosis of a Down syndrome patient is the starting point of an adequate management process that involves investigating possible associated comorbidities and their management on the one hand, and on the other hand the obligation of genetic counseling adapted to the case for the identification of other people with genetic risk in the proband family (29).

The cytogenetic results in patients with Turner syndrome (subgroup D) are relatively concordant with literature data. We found a high rate of X monosomy (complete or partial) mosaicism – 10/16 cases (62.5%) that are like data presented by Abulhasan *et al.* (1999) that discovered 22 cases with X monosomy mosaicism from 37 cases with Turner syndrome cytogenetically confirmed (59.45%) (30). Other reports that used large cohorts of patients with Turner syndrome presented different results, with an approximately frequency of X homogenous complete monosomy of 45% (31, 32). We consider that confirmation of clinical diagnosis in only 16 from 39 patients with Turner syndrome suspicion is correlated with the age of patients. Most of our patients were children and during childhood the only major symptom of Turner syndrome is the growth delay.

Our study showed the importance of use of different chromosomal analysis for confirmation of etiology of congenital anomalies. In 148 from 331 cases (44.71%) we discovered a chromosomal abnormality using only the karyotype or using the association of karyotype and FISH or MLPA. We consider that the use of karyotype remains the better approach for identification of chromosomal abnormality in aneuploid syndromes and in plurimalformative syndrome without a specific clinical pattern. If the patient has the characteristic features of a microdeletion/microduplication syndrome the first-choice analysis must be FISH or MLPA with specific probes and the use of karyotype is reserved to cases with possible derivative chromosomes. The array-CGH is a good method for characterization of genomic imbalances, but the high cost per analysis limits its use in practical medicine.

CONCLUSIONS

Elucidation of the chromosomal etiology of congenital anomalies is an important objective in their management, due to different recurrence risks depending on the chromosomal abnormality, and for identifying other individuals in the family at risk of

carrying a balanced chromosomal abnormality. The strategy of genetic testing is sequential, and usually must be started with the most simple and inexpensive technique that remains, the karyotype. In cases with clinical suspicion of a syndrome caused by a microdeletion, it is necessary to perform FISH or MLPA test for confirmation. If karyotype and/or FISH (MLPA) method does not identify a genomic imbalance it is important to apply array-CGH method that is able to confirm small genomic imbalances. However, because some congenital anomalies are produced by other factors (environmental, monogenic, polygenic) the application of all cytogenetic techniques – conventional cytogenetic methods (karyotype) molecular techniques (FISH, MLPA, array-CGH)–could remain without results and supplementary investigations are necessary.

EVALUATION OF THE EFFICACY OF SURGICAL RESECTION OF MALIGNANT GLIOMAS USING 5-AMINO-LEVULINIC ACID (Abstract): **Aim:** To evaluate the efficacy of a modern therapeutic procedure, surgical resection of malignant gliomas using 5-Amino-Levulinic Acid (5-ALA) compared with tumor resection associated with radiotherapy and/or antineoplastic medication. **Material and methods:** The investigation was performed on 127 patients diagnosed with malignant glioma, aged 20 to 80 years, admitted to the Neurosurgical Department of the Iasi "Prof. Dr. N. Oblu" Hospital between 2009-2015. Of these patients, 17 underwent surgical resection and 5-ALA (Gliolan®) treatment. 5-ALA was administered orally, 3 hours before the induction of general anesthesia, under the strict supervision of an anesthetist. The study protocol was approved by the Hospital Ethics Committee and informed consent was obtained from all patients enrolled in this study. A Kaplan-Meier analysis was used for the evaluation of therapeutic efficiency and assessment of the surviving subjects for a certain period of time after treatment. **Results:** Survival rate was significantly higher in the Gliolan® group compared to the group treated by classic methods at 6 months, 1 year, but especially after 2 years of treatment (0.65 vs 0.48). **Conclusions:** 5-ALA is a relevant intraoperative marker for direct visualization of the tumor and infiltrative tissue, providing the basis for a feasible future in the therapeutic management of glioblastoma and promising an increase in the survival rate compared to classic surgical method. **Keywords:** MALIGNANT, GLIOMA, 5-ALA.

In adults, malignant brain tumors account for approximately 2% of all neoplasms, their incidence increasing with age and declining in elderly patients aged over 75 (1, 2). Despite their relative rarity, primary central nervous system tumors are an important source of morbidity and mortality and still represent a major health problem (3). Researches on the etiology and the causes that contribute to the occurrence of gliomas are underway, but the relative rarity of the disease and the rapid death of the patients diagnosed with aggressive subtypes hamper these processes (4). Therefore, to date no causal factors are known and it is only assumed that exposure to therapeutic doses of ionizing radiation for the treatment of cancer results in an increased risk of glioma, as well as of meningioma, and nerve sheath tumors (5, 6). Different hereditary disorders or genetic mutations are also known to be involved in

the etiopathogenesis of gliomas (7).

In the literature, a link between cerebral trauma and brain tumors as a risk factor has been suggested. However, so far there is no conclusive evidence to support this assumption (3). On the other hand, it is considered that exposure to insecticides, pesticides, petrochemicals, organic solvents, lead compounds and nitro-derivatives increases the possibility of developing glioblastoma (8). Malignant brain gliomas are locally invasive tumors that inevitably lead to death within 1-2 years after diagnosis. These tumors remain associated with poor prognosis despite the maximum surgical treatment, completed with radiotherapy and chemotherapy. The degree of tumor resection is accepted as important for optimal surgical treatment, and recent studies provide evidence for a maximal cytological reduction in the management of newly diagnosed malignant gliomas (9, 10).

Patients with brain tumors may have different symptoms and clinical signs depending on their location, growth rate and presence of intracranial hypertension. The symptomatology associated with brain tumors is mainly determined by the tumor mass, adjacent edema, or normal brain tissue infiltration and destruction (11). Tumors positioned in functional areas of the cortex or along the ventricular system, with a high rate of growth, are clinically manifest shortly after onset, unlike those located in nonspecific areas, with late-onset manifestations (12). Among the most common symptoms are: headache, convulsions, sensory disturbances, motor or language deficits, confusion, personality changes, memory loss and visual deficits (11, 13).

Currently, treatment of malignant gliomas involves both surgical resection and multimodal treatment (radiotherapy, chemotherapy), considering that the best treatment option is to remove as much tumor volume as possible, while maintaining morbidity at a minimum level (14). There is increasing evidence that a maximum surgical cytoreduction (more than 98% of the initial tumor mass) is an important prognostic factor for patient survival, but this is not easy to achieve due to the infiltrative nature of these tumors (15). Despite the indisputable advances in imaging-guided surgical technique (neuronavigation), targeted radiotherapy and new chemotherapies (e.g. temozolamide, carmustine), the prognosis of patients diagnosed with malignant gliomas is currently gloomy, so it is imperative to develop new antitumor strategies (16, 17, 18). Remarkable discoveries in molecular biology and biotechnology, and particularly a better understanding of tumor biology (angiogenesis, apoptosis, immune response) open major possibilities for improving the prognosis of these patients. Biotech and especially biologic progress will open new attractive therapeutic targets to decrease the proliferation process of malignant brain tumors (14).

In the present study we **aimed** at evaluating the efficacy of a modern therapeutic procedure, surgical resection of malignant gliomas using 5-Amino-Levulinic Acid (5-ALA).

MATERIAL AND METHODS

We conducted a study of 127 patients diagnosed with malignant glioma, aged 20 to 80 years, admitted to Neurosurgical clinics (I, II, III) of the Iasi "Prof. Dr. N. Oblu" Hospital, between 2009 and 2015. Of these patients, 17 underwent surgical resection and 5-ALA (Gliolan®) treatment. 5-ALA was administered orally, 3 hours before the induction of general anesthesia,

under the strict supervision of the anesthetist. It is considered to be a relevant biomarker for the gross total resection of glioblastomas which has received approval for use in Europe since 2008 (19). The experimental protocol has been approved by the Hospital Ethics Committee, in accordance with the international regulations regarding the clinical trials and use of medical data, and the informed consent was obtained from all the enrolled patients. Inclusion criteria were: age over 18 years, diagnosis of malignant glioma confirmed by imagining methods. Exclusion criteria were: refusal of subjects or their family to be included in the clinical study, history of allergy to any of the 5-ALA compounds, porphyria, chronic liver disease, mental illness, non-cooperating patients. The following data were collected from all patients: socio-demographic data, clinical manifestations, biochemical parameters, tumor imaging and histopathologic appearance, therapeutic method used, efficacy of treatment over time, survival rate, relapses.

Evaluating the therapeutic efficiency and assessing the surviving subjects for a certain period of time after treatment was performed using the Kaplan-Meier analysis (20). This method (21) estimates data regarding the survival of patients with various diseases under a specific treatment, at different times during the investigation (especially when not all subjects continue the study). It also provides the comparative analysis of the efficacy of different applied therapeutic methods. In clinical trials, the effect of a therapeutic procedure is measured by counting the number of subjects surviving or being rescued at a specified time after applying the treatment. This type of analysis involves calculating the probability of occurrence of an event at a set time point (20).

The probability of survival at a given time point in the study is calculated using the following formula: (number of subjects living at the beginning of the study – number of deceased subjects) / number of subjects living at the beginning of the study (20).

Data were expressed as +/- standard deviation and significance was tested using un-paired t-test and Fisher`s method. P-values below 0.05 were considered statistically significant.

RESULTS

Kaplan-Meier's analysis revealed that patients with glioma who underwent surgery associated with Gliolan® treatment had a higher survival rate at 6 months, 1 year and 2 years, respectively, compared to the group without Gliolan®, treated using classic procedures (tumor resection associated with radiotherapy and/or antineoplastic chemotherapy). The survival rate was significantly higher in the Gliolan ® group (0.65), compared with the group treated by classic methods (0.48), especially after 2 years of treatment (fig. 1).

Statistical data analysis revealed that all 17 patients who were treated with Gliolan® survived 6 months after surgery.

Long-term monitoring of the subjects included in the study showed that: at the 6-month follow-up the disease recurred in 2 of the subjects; 15 of the patients survived 1 year after therapy (1patient with relapse); 11 of the patients treated with Gliolan® survived at 2 years (in 9 of them the disease recurred) (fig. 2, 3). Statistical data processing revealed that all 110 glioma patients treated by classic methods (radiotherapy and/or antineoplastic chemotherapy) survived 3 months after surgical intervention (fig. 4, 5).

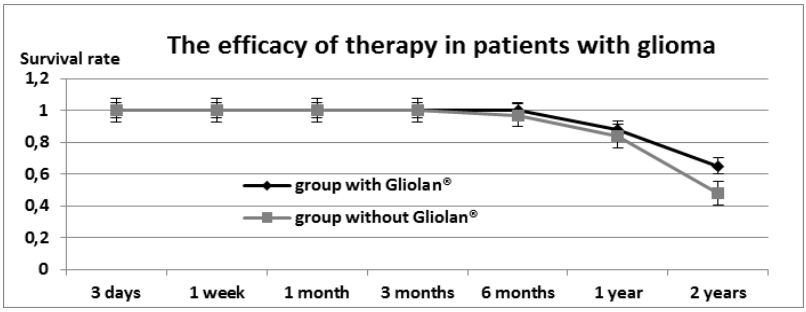

Fig. 1. Survival rate of patients with glioma according to the administered treatment

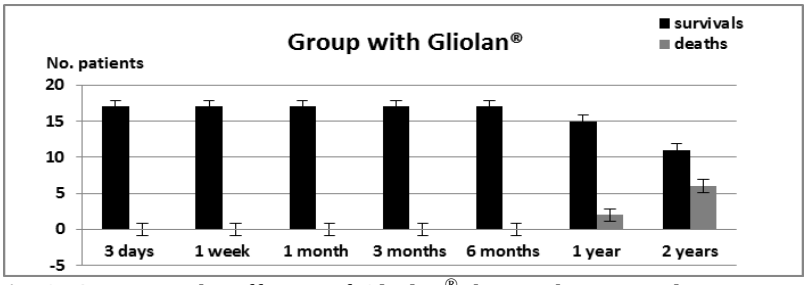

Fig. 2. Assessing the efficacy of Gliolan® therapy by survival rate in time

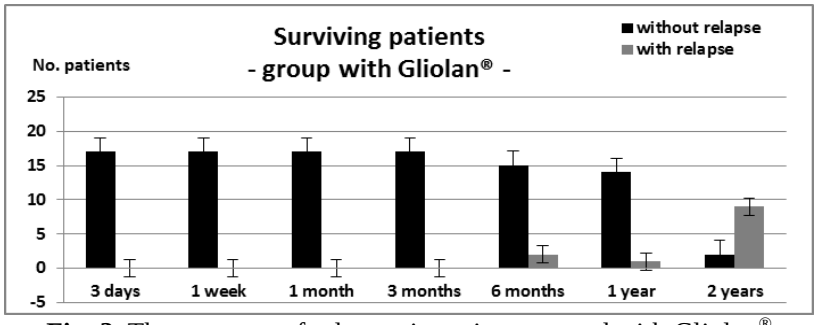

Fig. 3. The presence of relapses in patients treated with Gliolan®

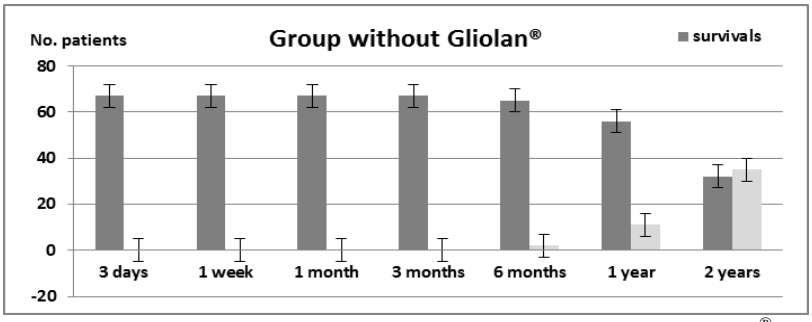

Fig. 4. Assessing the efficacy of classic therapy (without Gliolan®) by survival rate at 6 months, 1 year and 2 years after treatment

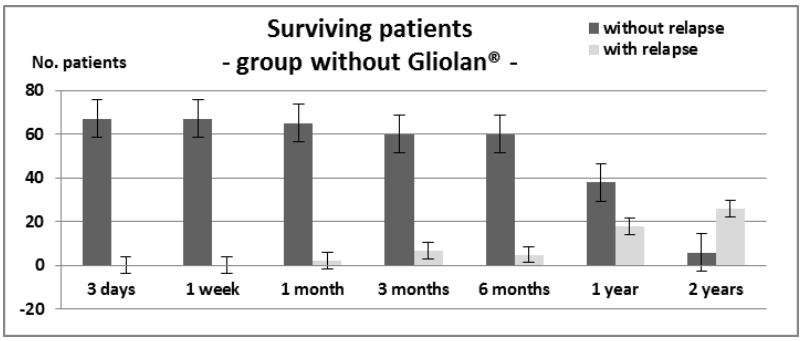

Fig. 5. The presence of relapses in patients without Gliolan®

The long-term assessment of the subjects included in the study showed that: one month after surgery the disease recurred in 2 patients; at the 3-month follow-up, it was found that the disease relapsed in 7 of the investigated patients; 65 patients survived 6 months after therapy (5 with relapses); 56 patients survived 1 year after therapy (in 18 the disease recurred); 32 patients survived at 2 years (but 26 presented disease relapse).

DISCUSSION

Over the past six decades, a variety of innovative techniques have been developed to help neurosurgeons and to increase the effectiveness of malignant brain tumor resections. Among these methods that have contributed to both improved and increased life expectancy, we mention: intraoperative electro-physiological monitoring, neuronavigations techniques, intraoperative ultrasound and magnetic resonance, and also fluorescein-guided cytoreductive surgery, involving the use of 5-aminolevulinic acid (9, 10).

Since its approval by the US Food and Drug Administration (FDA) in 2007, numerous studies have reported the use of 5-aminolevulinic acid in various brain tumors such as: meningioma, metastases or gliomas (19, 20). 5-Aminolevulinic acid is a natural compound produced in hemoglobin metabolism pathways, and its exogenous administration allows it to penetrate the blood-brain barrier and to be captured in neoplastic cells from both tumor and infiltration zones. By photodynamic action it induces apoptosis and tumor cell death, thus allowing maximum resection (23).

The steps taken to approve the use of this substance began after several clinical trials conducted in the neurosurgery departments of various university clinics which showed the benefits of maximal resection, with an improvement of the survival rate. In 2001, Lacroix M. (24) demonstrated an increase in the 5-month survival interval in patients with glioblastoma after maximum resection and treatment with Gliolan®. Four years later, Van den Bentet MJ (25) substantiated an increase in survival rate of 18.3 months in patients treated with Gliolan® compared with 13.5 months in those treated by the classical method, result which supports the efficacy of this substance.

CONCLUSIONS

In our clinical investigation we proved that intraoperative use of the navigation system has been of real help taking into account the changes that may occur, reach-

ing an accuracy of less than 1 cm, without altering the actual location of the tumor. This study showed that the survival rate was significantly higher in the Gliolan® group compared to the group treated by classic procedures, particularly 2 years after tumor resection. Based on the observations that 5-ALA is an important intraoperative marker for direct visualization of the tumor and infiltrative tissue, we can support the idea that it provides the basis for a feasible future in glioblastoma therapeutic management, promising an increase in survival rate compared to classic surgical method, by achieving a maximum resection.

NEWS

SYNTHESIS OF HIERARCHICAL CuO NANOSTRUCTURES: BIOCOMPATIBLE ANTIBACTERIAL AGENTS FOR GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA

Copper Oxide is one of the important materials among other antimicrobial agents such as silver, zinc oxide, or titanium dioxide. CuO nanostructures have stimulated great interest in the field of environmental remediation because of their important characteristics which include: high stability, structural properties, antimicrobial activity. The novelty of this study is the biocompatibiliy determination of nanostructured CuO. The findings of the present work proved that the prepared CuO nanostructures are highly stable in aqueous solution and biocompatible in blood. They also exhibited pronounced bactericidal activity towards both Gram positive and Gram negative bacteria (Sonia S, Jayasudha R, Jayram ND, et al. Synthesis of hierarchical CuO nanostructures: Biocompatible antibacterial agents for Gram-positive and Gram-negative bacteria. *Current Applied Physics* 2016; 16: 914-921).

HIDDED BEHIND AN EARLY REPOLARIZATION SYNDROME-CASE REPORT (Abstract): The electrocardiographic (ECG) pattern of "early repolarization syndrome" is no longer considered benign, mainly due to life-threatening rhythm disorders and sudden cardiac death sometimes associated to this syndrome. We report the case of a 55-year old man who was hospitalized after an episode of chest discomfort, emphasizing an aspect of early repolarization syndrome on electrocardiogram and diffuse ST segment depression at submaximal cycle ergometer test. However, the coronarography revealed severe distal occlusion of the left main artery including the origin of left anterior descendent and circumflex arteries. The revascularization treatment consisted of two drug eluting stents placed on left main artery, with good clinical and angiographic results. This association of severe coronary lesion hidden behind a benign ECG aspect has been rarely mentioned in the literature. **Keywords:** EARLY REPOLARIZATION, CORONARY ARTERY, LEFT MAIN, J POINT.

The "benign" label attached to early repolarization syndrome (ERS), defined as an electrocardiographic (ECG) pattern characterized by a prominent J-point and ST-segment elevation, notching or slurring (pseudo delta wave or late delta wave) of the end portion of the R wave with upward concavity ending in a positive high amplitude symmetric T-wave in most ECG leads, has been removed by Haïssaguerre et al. in 2008 (1). Recent evidences argue that ERS can be considered as part of a continuous spectrum of similar molecular, ionic and cellular mechanism expression, which may be generally referred to as "J-wave syndromes" (2). J wave syndromes are associated with amplification of the transient outward current (Ito)-mediated J waves that can initiate life-threatening ventricular arrhythmias (3). On the other hand, as cause of ST segment abnormality in Emergency Department, 12% of patients with chest pain have ERS on their ECG, thereby becoming a common diagnostic challenge for clinicians (4). ERS can mask the presence of acute ischemia, while lower R-wave amplitude, a higher ST-segment elevation and a longer QTc duration are arguments in favor of a subtle anterior STEMI (5). The common opinion is that between

ERS and ischemia there is no a direct causal relationship. Nonetheless, ERS was tagged in general conception as essentially benign. We report a case of severe ischemia generated by the presence of a tight left main stenosis appeared on an initial ECG as ERS.

CASE REPORT

A 55-year-old Caucasian male, construction worker, current smoker, chronic drinker (gamma glutamyl trans peptidase 35 UI/ml), without a personal or hereditary history of cardiovascular diseases comes to the Emergency Department and was referred to the Cardiology Clinic for a new onset of chest discomfort occurring at effort, disappearing at rest, radiating to the left arm, lasting for more than 20 minutes, that was progressively intensified in the last week. At admission, he was hemodynamically stable, with blood pressure of 140/90 mmHg, without significant tensional difference between the right and left arms, heart rate of 55 bpm and normal peripheral pulse. Further physical examination showed normal weight patient (BMI 24.5 kg/m²) and temperature 36.8^0 C, without any pathological findings or neurological deficits. His standard 12-lead electrocardiogram (ECG) (fig. 1) shows a sinus bradycardia 55 bpm, concave ST elevation in the precordial leads (V_2-V_6), with notching and slurring at the J-point, prominent, slightly asymmetrical T-waves that are concordant with the QRS complexes. No previous ECG of the patient was available to see whether ERS was present before.

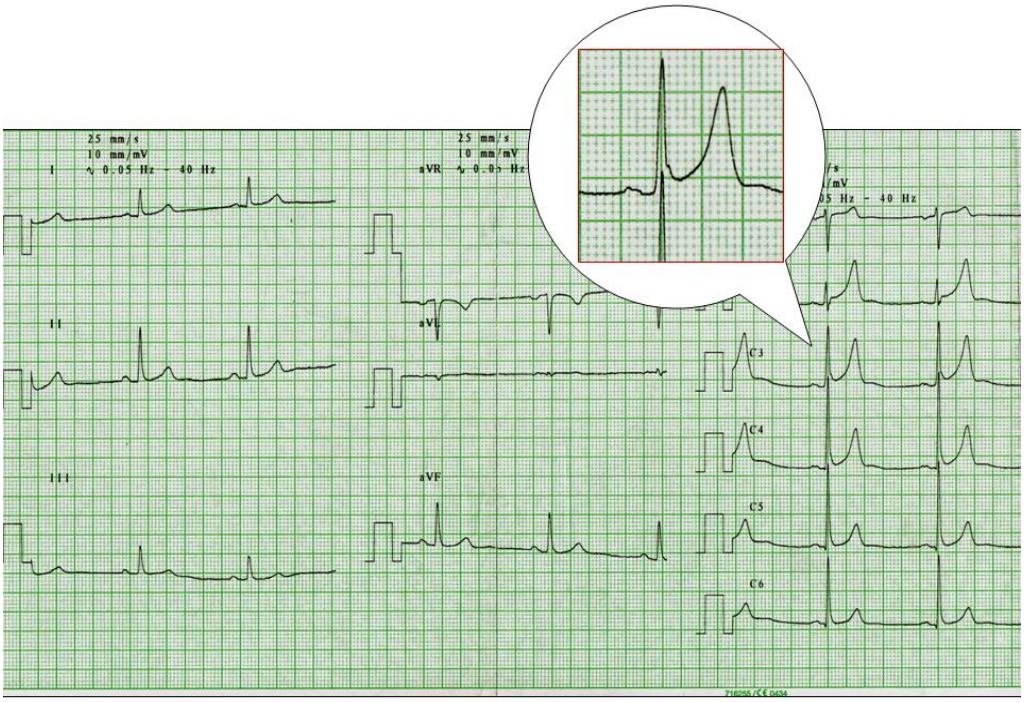

Fig. 1. 12-leads ECG: sinus bradycardia 55 bpm, high R wave in V_2, concave ST elevation in the precordial leads (V_2-V_6), with notching and slurring at the J-point, suggestive for an ERS.

The degree of ST elevation is modest compared to the T-wave amplitude. ST elevation is below 2 mm in the precordial leads. No reciprocal ST depression to suggest STEMI. Should be noted that, per literature, this ERS pattern (ER followed by rapidly upsloping ST segments after the J point) is not associated with an increased risk for arrhythmic death (6), contrary to ERS associated with horizontal or descending ST segments after the J point. ST changes were relatively stable over time, with no progression on serial ECG tracings. Laboratory analysis showed dyslipidemia (serum cholesterol 306 mg/dL, HDL-C 43 mg/dL, LDL-C 233 mg%, triglycerides 152 mg/dL) and negative cardiac biomarkers (creatine phosphokinase 78 ui/l, creatine phosphokinase-MB 15 ui/l, troponin I 0.001 ng/ml), with normal liver (serum glutamate-pyruvate transaminase 25 ui/l and serum glutamate-oxaloacetate transaminase 16 ui/L) and renal (BUN 37 mg/dL, serum creatinine 0.7 mg%) function, without anemia (hemoglobin 15.2 g%, hematocrit 45.7%). Chest discomfort was quickly removed after nitroglycerin spray (0.4 mg) administration. Thereafter, the patient was admitted as unstable angina and received loading doses of clopidogrel and aspirin upon admission continued with aspirin 75 mg o.d., clopidogrel 75 mg o.d., enoxaparin 60 mg bid, nebivolol 5 mg o.d., perindopril 10 mg o.d. and atorvastatin 80 mg o.d..

The rapid control of chest pain in a patient with cardiovascular risk factors (chronic smoker with hyperlipoproteinemia) with ECG changes suggestive of early repolarization syndrome and considering that programming for coronary angiography implies registration on a long waiting list has led us performing, for shaping the diagnosis, the cycle ergometer exercise test (fig. 2). Nebivolol was not discontinued prior to performance of the stress test. Exercise stress testing electrocardiogram showed ST-segment depression in eight leads with elevation in leads aVR and V_1, suggestive for subendocardial ischemia related to three-vessel or left main coronary artery disease: positive submaximal exercise test with the occurrence of chest pain associated with a ST-segment horizontally depression (1-2 mm) at 60 W in leads V_4-V_6, then V_3-V_6, sharp changes in the recovery period, ST segment depression in inferior leads and ST elevation in aVR and V_1. Maximum BP was 160/90 mmHg, HR maximum 92 bpm.

The patient was urgently directed to a PCI center where angiography was performed and revealed: distal sub occlusion 99% of the left main coronary artery (LMCA) including the origin of left anterior descendent (LAD) and circumflex (Cx) arteries, dominance of the left coronary bed, a 60% plaque of the first marginal artery and 30% plaque on the right coronary artery (fig. 3). The interventional cardiologist has decided to perform within the same session the coronary angioplasty.

The percutaneous coronary intervention procedure included (fig. 4) the predilatation of the distal left main artery toward LAD and placement of a Promus dug eluting stent (DES) (PROMUS™ Everolimus-Eluting Coronary Stent, Boston Scientific Corporation). The post-dilatation was performed by using kissing balloon technique toward LAD (3.5/15 mm, 8 atm) and toward Cx (2.5/20 mm, 12 atm) arteries and a Taxus DES (TAXUS™ Element™ Paclitaxel-Eluting Coronary Stent System, Boston Scientific Corporation) implantation in the ostium of Cx (3.0/16 mm, 14 atm). The result was very good. A 7-day double-dose clopidogrel regimen after

procedure was administered according to CURRENT trial (7) where in patients undergoing PCI for acute coronary syndromes this regimen was associated with a reduction in cardiovascular events and stent thrombosis compared with the standard dose. Subsequently, the patient was recommended clopidogrel 75 mg o.d. for 24 months after stenting and aspirin 75 mg o.d. lifelong.

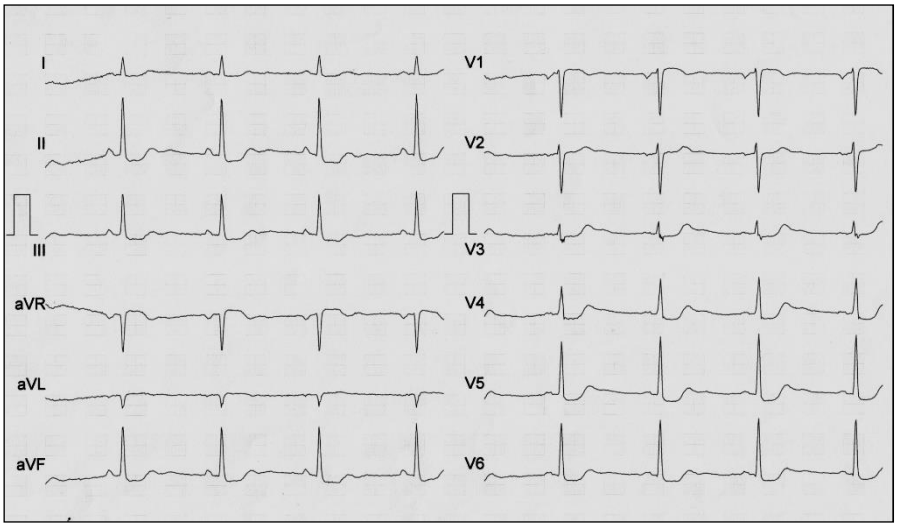

Fig. 2. Exercise stress testing electrocardiogram of the patient with angina without elevated cardiac biomarkers: ST-segment depression in eight leads with elevation in leads aVR and V_1 suggestive for subendocardial ischemia related to three-vessel or left main coronary artery disease.

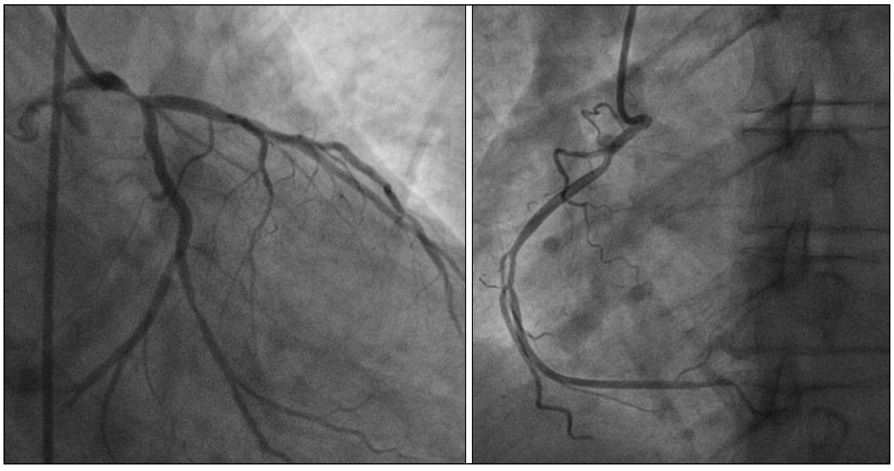

Fig. 3. Coronary angiography: distal sub occlusion 99% of the left main artery (LMCA) including the origin of left anterior descendent (LAD) and circumflex (Cx) arteries. Right coronary artery with no significant plaques.

Fig. 4. Coronary angioplasty: pre-dilatation of LMCA and a DES placement; post-dilatation using kissing balloon technique toward LAD and Cx arteries with a DES implantation in the ostium of Cx.

DISCUSSION

The relationship between ERS and fatal arrhythmias, that once seemed a heresy, nowadays is accepted and intensively studied: the assuasive electrocardiographic pattern was acknowledged to be a marker of hidden risk. Probably, it would worth being reviewed the relationship between J wave syndromes and myocardial ischemia. Currently, the following assertions may be formulated about ERS:

Firstly, ERS is an ECG pattern quite frequently encountered: Tikkanen et al, in a study involving 10.864 middLe-aged subjects, found a prevalence of ERP of 5.8% (8).

Secondly, there are some recent attempts to redefine the ERS definition on much stricter criteria (9) established with the peak of an end-QRS notch and/or the onset of an end-QRS slur (Jp) that must be determined when an ERS is suspected. To certify its presence, the presence of a Jp ≥ 0.1 mV is mandatory, while ST-segment elevation is no more a required criterion.

Thirdly, there was a debate whether J wave syndromes are repolarization or depolarization/conduction abnormalities (10). J waves as repolarization components are commonly seen in young males with structurally normal hearts, while depolarization/conduction abnormalities are commonly found in elderly with structural heart diseases. Nonetheless, Antzelevitch et al. tried to solve this issue (11).

Fourthly, a relationship between ventricular fibrillation and J wave with ERS was demonstrated in a relatively large number of patients (1). Left precordial terminal QRS notching is prevalent in ma-

lignant variants of ERS and could be used as a tool for risk stratification (12). ERS in the inferior leads was at borderline significance in predicting cardiac and death of all-cause (8). Moreover, J-wave dynamics can be sometimes involved in the generation of ventricular fibrillation (12).

Fifthly, referring to the relationship between ERS and ischemia, the available data are often unclear. The association, coincidentally or not, between ERS and ischemia has few reports. Yan and Antzelevitch point out that myocardial ischemia is known to reduce inward currents and to increase the outward potassium currents particularly by intensifying I_{to} especially in the epicardium, thus possibly unmasking J waves (13). A relationship between ERS and myocardial ischemia has been mentioned cases of coronary spasm (14, 15) which can cause fatal ventricular arrhythmias or sudden cardiac death. The augmentation, development and altered J-wave dynamics may be related to the heterogeneous distribution of transmural ventricular repolarization in patients with myocardial ischemia induced by provoked coronary spasms (14). There are arguments in favor of the assumption that a type of acquired J wave syndrome is "ischemia-induced J wave syndrome", as shown by a series of studies published in China (16, 17). The mechanisms underlying ischemia-induced J wave must be better understood because sudden arrhythmic death is the major cause for mortality associated with acute coronary syndrome (3). On the other hand, the importance of differentiating between acute ischemic changes and ERS true benign pattern must be underlined: in benign ERS reciprocal ST segment changes are possible only in lead aVR in contrast to the idiopathic ventricular fibrillation and acute coronary syndrome where reciprocal ST segment changes can be observed in several leads (18). Moreover, in benign ERS the ST segment and T wave patterns have a relative temporal stability (18).

In our reported case, ERS changes were diffuse (inferior and precordial leads). Perhaps the cycle ergometer exercise test was a bit bold in this case, but the positivity led to further invasive investigations in emergency. Moreover, the interventional cardiologist has decided to perform a complex percutaneous intervention which was prohibited a couple of years before. The immediate and long-term outcomes after stenting the LMCA stenosis in patients with normal left ventricular (LV) function have been demonstrated to be excellent (19), evolution like our case. It is worth mentioning that the initial ECG aspect has not changed after PCI.

It is possible that some cases of sudden death are due to ERS associated to severe ischemic substrate, such as LMCA lesions. The hypothesis that a diffuse distribution of ERS-like pattern is associated with left main or tri-vessels lesions, especially in patients with positive exercise stress test, must be validated by further studies.

CONCLUSIONS

Our case report shows that a seemingly benign ECG pattern can hide a serious coronary lesion, especially in patients with chest pain, in whom it is important to complete the usual diagnostic algorithm with at least an exercise stress test. Reflecting on the link between ERS and ischemia it is worth wondering whether some of the cases of sudden death might have occurred in the context of such so-called "benign" ECG pattern that could have appeared on a severe ischemic substrate, such as left main lesion.

COMPARATIVE STUDY OF HYSTEROSCOPY AND 3D ULTRASOUND FOR DIAGNOSING UTERINE CAVITY ABNORMALITIES (Abstract) **Objective**: Hysteroscopy is the most accurate method for diagnosing intrauterine pathologies related to abnormal bleeding and infertility. The accuracy of three-dimensional (3D) ultrasonography and hysteroscopy were compared in identifying uterine cavity abnormalities. **Material and methods**: A total of 139 cases of abnormal uterine bleeding or infertility first had two-dimensional and 3D ultrasound performed before hysteroscopy. Findings on 3D ultrasound and hysteroscopy were compared, and sensitivity, specificity, positive predictive value, negative predictive value, and likelihood ratio were calculated. **Results**: Mean patients' age was 36.5 (+/- SD 9.04). Three-dimensional ultrasound had a sensitivity of 88%, specificity of 94%, a positive predictive value of 96%, negative predictive value of 84%, likely ratio of 5,5, and accuracy of 90% in diagnosing uterine cavity abnormalities. Three-dimensional ultrasound had a high sensitivity and specificity for polyps (97% and 97%, respectively), congenital uterine malformations (100% and 99%, respectively) and submucous myoma (87% and 100%, respectively), but a low sensitivity and high specificity for uterine synechia (41% and 99%, respectively). **Conclusions**: For diagnosing uterine cavity anomalies, 3D ultrasound is a useful tool and could replace diagnostic hysteroscopy for certain conditions, such as congenital uterine anomalies. **Keyword**: HYSTEROSCOPY, THREE-DIMENSIONAL ULTRASOUND, UTERINE CAVITY ABNORMALITIES.

Abnormal uterine bleeding and infertility are two of the most common complaints in gynecologic practice. To properly diagnose and manage both conditions, assessing the uterine cavity for possible abnormalities is essential. Transvaginal ultrasonography is the standard method for screening for possible endometrial or uterine cavity abnormalities. When indicated, saline/gel infusion sonography, hysterosalpingography, or hysteroscopy may also be used to evaluate the uterine cavity lining. Hysteroscopy is widely accepted to be the most accurate method for investigating the uterine cavity (1, 2).

Three-dimensional (3D) ultrasound is a new technology that allows us to examine pelvic structure and their volumes with great accuracy. The main advantage 3D ultrasound confers is the ability to obtain a view of the coronal plane of the uterus (3), which, in turn, may be used to locate the

position of intrauterine pathology. Therefore, 3D volume ultrasound is superior to two-dimensional (2D) sonography in identifying uterine cavity abnormalities.

Our study aimed to compare 3D ultrasound with hysteroscopy in assessing the uterine cavity and to find a place for this technology in gynecologic practice.

MATERIAL METHODS

Our study included 139 women attending our university hospital for hysteroscopy. The main indications for hysteroscopy were abnormal uterine bleeding and infertility. Before hysteroscopy was scheduled, transvaginal 2D and 3D ultrasound examinations were performed for each patient. For both examinations, we used 3D endovaginal ultrasound probes (RIC6-12D, 4-8Mhz, Voluson E8 and RIC 5-9H Voluson 730 Pro, GE Healthcare). The ultrasound examination began with a conventional 2D ultrasound. First, the uterus was localized and its position was noted, then the uterus was measured in three planes (longitudinal, coronal, transverse). Endometrial thickness was measured in the longitudinal plane, including the two layers at its maximum thickness. Then, the adnexal region was scanned to identify the ovaries, fallopian tubes, or adnexal pathology. The 3D volume was obtained longitudinally along the length of the uterus. The coronal plane of the uterus was obtained using the Abuhamad technique (4). For patients with infertility, the ultrasound examinations were scheduled in the follicular phase of their menstrual cycles (Days 3-10). Informed consent was obtained from all patients.

A 5-mm outer-diameter continuous flow Bettocchi hysteroscopy was used with a 30° direction of view (Karl Storz Endoscopy). Normal saline solution was used for distension of the uterine cavity at a pressure of 20-50 mm Hg. The hysteroscopy procedures were performed under local and/or general anesthesia. Systematic inspection of the uterine cavity was done, and internal os and cervical canal were visualized. The hysteroscopically detected intrauterine abnormalities were defined as endometrial polyps, submucous myomas, endometrial hyperplasia, intrauterine adhesions, or uterine congenital anomalies, such as arcuate or septate uterus. Treatment consisted of removal of polyps, myomas, adhesions, or septa using scissors, grasping forceps, or a resectoscope (Karl Storz Endoscopy). After the intervention, a detailed record was completed with information about patient tolerance, diagnostic findings, and treatment.

Statistical methods

Data was statistically represented in terms of range and mean standard deviation (+/- SD) and percentages. Accuracy was represented using the terms of specificity, sensitivity, positive predictive value, negative predictive value, likely ratio, and overall accuracy. The statistical data were calculated using the Microsoft Excel (Microsoft Corporation, NY, USA). Diagnostic accuracy of hysteroscopy and 3D ultrasound for different intrauterine pathologies were compared using tables.

RESULTS

A total of 139 patients with abnormal uterine bleeding, primary infertility, or secondary infertility were included in the study (Table 1). The patients' mean age was 36,5 +/- 9,04 years old. Abnormal uterine bleeding included cases of menorrhagia, metrorrhagia, hypomenorrhea, and postmenopausal bleeding (Table 2). A

comparison of the uterine anomalies detected using 3D ultrasound and hysteroscopy are shown in Table 3.

In diagnosing uterine cavity abnormalities, 3D ultrasound has a sensitivity of 88%, specificity of 94%, a positive predictive value of 96%, negative predictive value of 84%, likely ratio of 5,5 and accuracy of 90%. When we analyzed different uterine cavity pathologies, we observed a high sensitivity and specificity of 3D ultrasound for polyps (97% and 97%, respectively), myoma (87% and 100%, respectively), and uterine congenital abnormalities (100% and 99%, respectively), but a low sensitivity for uterine synechia (41%) (tab. IV).

TABLE I

Patients' Indications for Hysteroscopy

Indications for hysteroscopy	Number of cases	Percentage
Primary Infertility	51	36,71%
Secondary infertility	42	30,21%
Abnormal uterine bleeding	46	33%
Total	139	100%

TABLE II

Type of abnormal uterine bleeding

Symptoms	Number of cases	Percentage
Metrorrhagia	8	17,3%
Menorrhagia	20	43,47%
Menorrhagia and Metrorrhagia	9	19,57%
Postmenopausal bleeding	9	19,57%
Total	46	100%

TABLE III

Anomalies Detected using 3D Ultrasound and Hysteroscopy

Type of Anomaly	3D Ultrasound	Hysteroscopy
	No. Cases	No. Cases
Endometrial polyp	45	44
Endometrial hyperplasia	8	7
Submucous myoma	7	8
Uterine congenital anomalies	7	6
Osseous metaplasia	2	2
Uterine synechia	8	17
Uterine neoplasm	1	1
Uterus normal	61	54

TABLE IV
Sensitivity, specificity, positive predictive value and negative predictive of 3D ultrasound value for different uterine cavity pathologies.

Uterine anomaly	Sensitivity	Specificity	PPV	NNV
Polyp	97%	95%	95%	98%
Myoma	85%	99%	100%	99%
Congenital anomaly	100%	99%	85%	100%
Synechia	44%	100%	87%	92%

DISCUSSION

Abnormal uterine bleeding and infertility are two of the most common complaints in gynecology. Their management depends on diagnostic accuracy, and the first step is evaluating the uterine cavity. The basic work-up consists of transvaginal sonography possibly followed by hysterosonography, hysterosalpingography, or hysteroscopy to directly assess the uterine cavity.

Hysteroscopy is generally considered to be the gold standard in diagnosing intrauterine pathologies, including endometrial polyps, submucous myomas, intrauterine adhesions, and uterine septa (5). Compared to histopathology or hysterectomy findings, hysteroscopy is very accurate for diagnosing intrauterine abnormalities (6). One advantage of hysteroscopy is the possibility of performing a directed biopsy or a small surgical intervention during the same session (5). Also, in more recent years, hysteroscopy has been increasingly performed in an outpatient setting, which is highly acceptable and popular with patients. Office hysteroscopy has increasingly been recommended as a routine procedure in infertility evaluation (7, 8, 9, 10). After repeated implantation failure during in vitro fertilization cycles, the uterine cavity should be reevaluated using hysteroscopy; this practice has been demonstrated to improve pregnancy rates (6, 11, 12). However, hysteroscopy is an invasive procedure, and complications, such as uterine perforation and ascending genito-urinary infections, although very rare, can still occur (13, 14).

Because transvaginal ultrasound is a common and noninvasive procedure, its role in diagnosing uterine cavity anomalies should not be neglected. Although hysteroscopy is the gold standard, 2D transvaginal ultrasound has a sensitivity of 78.15% and specificity of 44.4% in detecting cavity abnormalities (15). However, 2D sonography cannot confidently diagnose submucosal fibroids in a uterus with multiple fibroids, distinguish between a hyperplastic endometrium and a large polyp, nor differentiate between an arcuate and a septate uterus (16, 17). These limitations can be overcome by 3D ultrasound, which has become more important in recent years in gynecology and obstetrics.

First introduced in the 1980s, 3D ultrasound has taken some time to be adopted. In 1993, a transvaginal application was developed, which allowed the acquisition of 3D surface images of the uterus and ovaries (18). The main advantage of 3D ultrasound is the ease in obtaining the coronal view with the entire endometrial cavity, the relationship of the endometrium to myometrium, and the uterine serosa. Compared to using 2D slices, the ability to ob-

tain and navigate through the 3D coronal views of the uterus allows the clinician to visualize the cavity more precisely and accurately. Three-dimensional ultrasound with surface- and transparent-mode reconstructions of the uterus has reported advantages over conventional 2D scanning. In experienced hands, a sensitivity of 93% and a specificity of 100% have been achieved (19).

In our study, compared to hysteroscopy in diagnosing uterine cavity abnormalities, 3D ultrasound has a sensitivity of 88%, specificity of 94%, a positive predictive value of 96%, negative predictive value of 84%, likely ratio of 5,5, and accuracy of 90%. Using transvaginal 2D sonography or hysterosalpingography, Sylvestre et al. studied 209 subfertile patients who were thought to have an intrauterine lesion (20). Using saline infusion sonography with 2D and then 3D sonography, 92 patients were subsequently identified as having a variety of intrauterine lesions, suggesting a sensitivity and specificity of 97% and 11%, respectively, for 2D sonography, 87% and 45%, respectively, for 3D sonography, and 98% and 100%, respectively, for 2D saline infusion sonography.

In our study, when analyzing different uterine cavity pathologies, 3D ultrasound had a high sensitivity and specificity for identifying polyps (97% and 97%, respectively), myoma (87% and 100%, respectively), and congenital uterine abnormalities (100% and 99%, respectively) (fig. 1, 2). In cases with synechia, 3D ultrasound had a low sensitivity (41%). The low sensitivity for synechia could be explained by the timing of the ultrasound. The ultrasound was performed during the follicular phase of the menstrual cycle when the endometrium was thin. Performing transvaginal sonography at midcycle (three-layer endometrium) rather than after menstrual cessation when endometrial thickness is less than 3 mm enables better imaging of small intrauterine adhesions (17). Also, in cases with synechia that were not detected by ultrasound, the adherence was very fine and minimal; this could be another reason why they were misdiagnosed during ultrasound examination.

c. Hysteroscopic image of the myoma.

La Torre et al. compared 3D sonography with conventional 2D imaging with and without saline contrast in their study of 23 patients in whom subsequent hysteroscopy revealed the presence of 16 endometrial polyps (21). Standard 2D sonography demonstrated a relatively poor specificity of only 69.5%, suggesting the presence of polyps in 23 patients. In contrast, 3D sonography diagnosed 18 polyps, with a specificity of 88.8%, and 3D hystero-sonosalpingography diagnosed 16 polyps, per hysteroscopic and histologic findings, with a specificity of 100%. Another prospective study of 70 patients that compared 3D ultrasound with hysteroscopy in premenopausal bleeding found that 3D ultrasound had a sensitivity of 63.2%, specificity of 80.8%, positive predictive value of 54.6%, negative predictive value of 85.7%, and accuracy of 76.1% (22).

In our study, 3D ultrasound proved to be very accurate for diagnosing uterine congenital anomalies, in agreement with the literature. Ghi et al. consider 3D ultrasound to be extremely accurate for the diagnosis and classification of congenital uterine anomalies and suggest that it may become the only mandatory step in the assessing the uterine cavity in patients with a history of recurrent miscarriage (23). The advantage of 3D ultrasound over hysteroscopy is that it can show the external contour of the uterus and can differentiate septate uterus from bicornuate uterus. In addition, 3D ultrasound is superior to 2D views in identifying the exact location of endometrial polyps and the degree of protrusion of a submucous fibroid into the cavity, as well as the amount of myometrium remaining outside of the submucous fibroid. In recent years, hysteroscopic resection of submucous fibroids has become an accepted method for treating premenopausal women with a history of abnormal uterine bleeding. The success and safety of this operation depends largely on the accurate preoperative assessment of the position of the submucous fibroid in relation to the uterine cavity (24). Before planning surgery for uterine myoma, 3D ultrasound could be an essential tool because it can provide precise information regarding the size of the myoma and the depth of myometrial exten-

sion. Moreover, 3D is useful also during post-surgical management.

CONCLUSIONS

Hysteroscopy remains the gold standard for diagnosing uterine cavity anomalies. However, 3D ultrasound has high sensitivity and specificity for uterine cavity anomalies and should be used a primary screening tool. Although 3D ultrasound has a low specificity for uterine synechia, it has a high specificity for uterine congenital anomalies. Further, 3D ultrasound is useful before planning an intervention on the uterine cavity, especially in cases of congenital anomalies and uterine fibroma.

NEWS

CLOPIDOGREL AND THE ENDOTHELIAL FUNCTION – BEFORE AND AFTER

The conclusion of a recent article published in the Journal of American Heart Association is that the administration of Clopidogrel in healthy people with high platelet aggregation improved the microcirculatory endothelial function and it apperas to have additional vascular benefits. The researchers evaluated the platelet activity of the healthy persons, a group of 287/241 Old Order Amish, before and after the administration of Clopidogrel for 7 days, quantifying it by laser Doppler flowmetry (LDF) mediated by thermal hyperemia and postoclussive reactive hyperemia. The results showed that Clopidogrel influenced only LDF mediated by thermal hyperemia, having a bigger impact on women than men; also, the evaluation before Clopidogrel showed that women have a higher platelet aggregation (Salimi S., Lewis J.P. et al. Clopidogrel Improves Skin Microcirculatory Endothelial Function in Persons With Heightened Platelet Aggregation. *J Am Heart Assoc.* 2016; 5:e003751).

EXPERIMENTAL MODEL OF MIXED INTESTINAL INFARCTION IN RABBIT (Abstract): The article presents an experimental model of the mixed intestinal infarction obtained by ligaturing of the cranial mesenteric artery (CMA) and of the cranial mesenteric vein (CMV) in rabbit. **Keywords**: RABBIT, INTESTINAL INFARCTION, EXPERIMENTAL MODEL

Acute mesenteric ischemia (AMI) consists of interruption of the blood flow in the irrigation area of the superior or inferior mesenteric artery, that results in intestinal infarction (1).

The first description of mesenteric vascular occlusion was attributed to Antonio Beniviene from Florence in the latter part of the fifteenth century (2). Little progress was made until 1895, when Elliot reported the first patient recover following resection of infarcted intestine (3).

In 1926, Cokkinissaid: „*Occlusion of the mesenteric vessels is apt to be regarded as one of those condition of which* […] *the diagnosis is impossible, the prognosis hopeless and the treatment almost useless*" (4). However, the progress in understanding of the pathophysiology and diagnosis, has made it possible to save sometimes the lives of patients with mesenteric ischemia.

For the physio pathological study of intestinal ischemia/ perfusion injury, the following animals are mainly used in experimental models: mice (5), rat (6-7), rabbit (8-9), pig (10).

In this study, the mixed intestinal infarction was reproduced in rabbits by ligaturing simultaneously the cranial mesenteric artery (CMA) near the emergence and by ligaturing the cranial mesenteric vein (CMV) near its pouring point in the portal vein. The abdominal topography of the rabbit presents some particularities: the cecum occupies a considerable part of the dextroventral half of the abdominal cavity, the spleen is positioned on the caudomedial surface of the stomach, and the kidneys are asymmetrically positioned in the retroperitoneal space – the right kidney lays between the planes through the 10-11 intercostal space and through the first lumbar

vertebra, the left kidney is between the 2nd and the 4th lumbar vertebra (11). CMV is direct constant affluent of the portal vein, that helps its marking (12).

In humans, the vascular mixed mesenteric obstruction is realized rather by an extrinsic compressive mechanism: tumors from near surrounding structures, of the mesenteric roots, of the duodenojejunal flexure (13), incarcerated trans mesenteric intestinal hernia (14), aortic aneurysm situated in the pouring point of the mesenteric artery. The double occurrence in artery and vein through intrinsic mechanism is rarer found (in mesenteric vasculitis (15-16)). Some authors consider the mixed form an evolutive stage of the arterial or venous infarction (17).

MATERIAL AND METHOD

All experimental procedures were performed in the Experimental Medicine Center, "Iuliu Haţieganu" University of Medicine and Pharmacy, Cluj-Napoca, with approval of the Ethical Commission of the university. Seven adult Californian rabbits (*Oryctolagus cuniculus sp.*) in two lots: A–experiment (five rabbits) and B–control (two rabbits, which were undertaking the same preoperative procedures and anesthetics like the rabbits from group A).

In order to eliminate from the study, the animals with abdominal pathology or vascular malformation of the cranial mesenteric package, the preoperative exam included veterinarian clinical examination, abdominal x-ray (fig. 1) and abdominal ultrasound. For the ultrasonography, we used a GE Logiq S7 machine, with a 6-15 MHz matrix transducer. We used the B mode to identify and assess the morphology of the vessels (fig. 2). We used color Doppler flow mode to visualize the direction and the laminar nature of the blood flow and we measured the velocities and flow indexes using spectral Doppler (fig. 3-4).

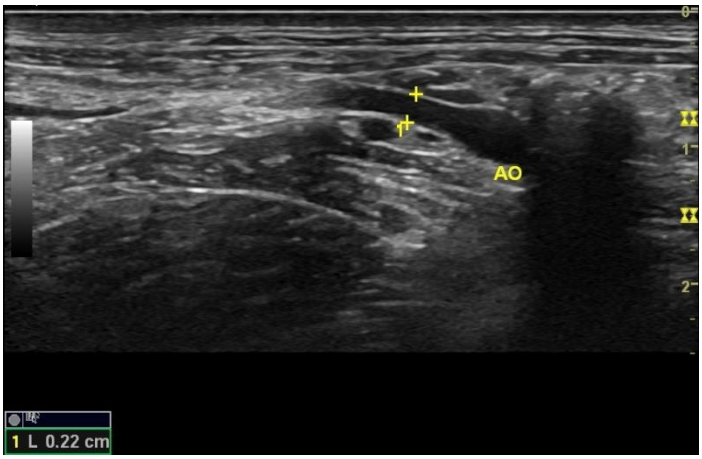

Fig. 2. Ultrasound identification of CMA emerge and measuring of its diameter.

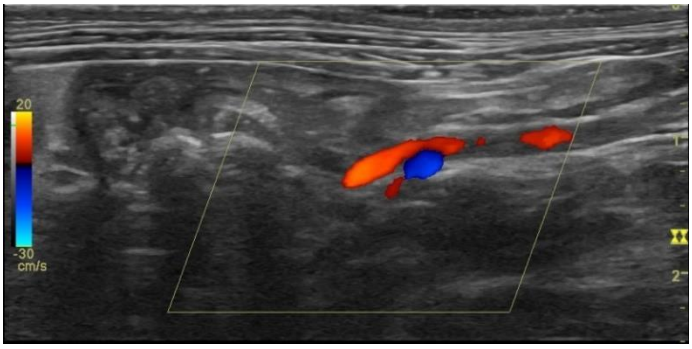

Fig. 3. Doppler ultrasound identification of the cranial mesenteric vascular package – CMA (red), CMV(blue).

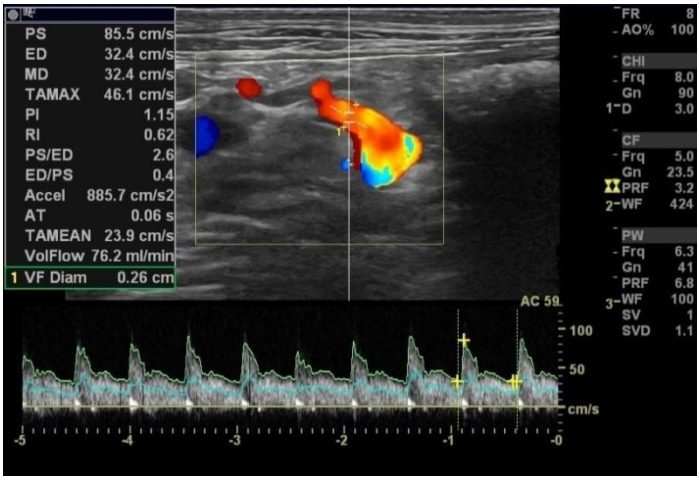

Fig. 4. Doppler ultrasound measuring of hemodynamic parameters in CMA.

Preoperative diet consisted in food deprivation for 24 hours, with hydration.

Preoperative, abdominal fur was shaved off.

Induction of anesthesia was performed with Ketamine 100 mg/ml, 0,35 ml/kg body weight and Xylazine 20 mg/ml, 0,15 ml/kg body weight, after which the animal was bound on the operating table in a dorsal decubitus position (fig. 5).

Fig. 5. The animal on the operating table in a dorsal decubitus position.

The surgical instrument set was made out of cutting and stinging instruments (scalps, electrocautery, straight and curved scissors), hemostatic forceps, dissecting forceps, anatomical forceps, surgical forceps, microsurgical instruments, Farabeuf retractor, instruments for sewing tissues. Preoperative, the instruments were sterilized through boiling for 60 minutes at 110°C in an electric boiler.

After preparing and isolating the surgical field, laparotomy was preformed through midline incision.

While exploring the abdominal cavity, the aspect and the viability of the intestine, the presence of the peristalsis was followed. After the exteriorization of the intestine through the surgical incision and it's flapping towards the right side, the left kidney was looked for as a reference point and the retroperitoneal adipose tissue was penetrated. Following the left renal artery, path the aorta was localized and through its discovery, overlying the emerge of the left renal artery, the CMA was identified, easily mobilized by the movement of the mesentery and intestine. After the discovery of the CMA for a length of ca. 5mm from the emergence (fig. 6), the CMA was ligatured with a non-absorbable 4.0 (fig. 7) and the absence of the pulse distal to the ligature was verified.

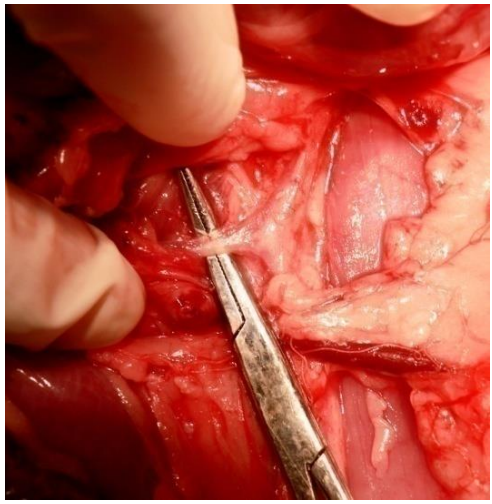

Fig. 6. Discovery of CMA, mobilization through light pulling of mesentery.

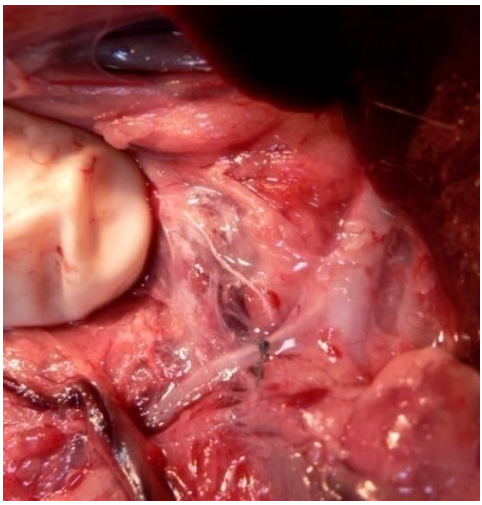

Fig. 7. Ligaturing of CMA.

After flapping the intestine on the left side, near to the CMS, the CMV was identified. After its isolation, CMV was ligatured with non-resorbable 4.0 (fig. 8).

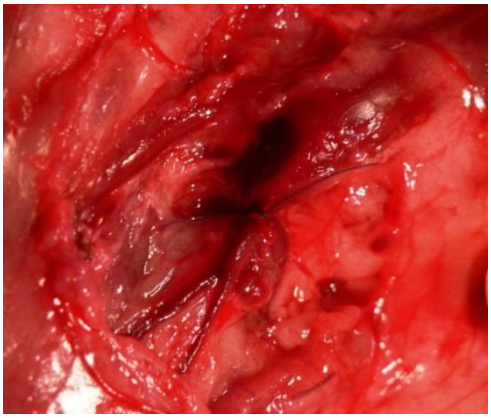

Fig. 8. The CMV ligature close to its entry into the portal vein.

During the intervention the intestine was covered by sterile compresses soaked in physiologic salt solution.

After ligaturing, the abdominal cavity was washed with physiological salt solution which was warmed to 37°C. The laparoraphy was performed in anatomical layers with non-resorbable 2.0.

Post operatory, the rabbits were put into recently cleaned and disinfected cages.

RESULTS

Intraoperatory and post operatory observations. The clinical state of the animals was permanently supervised intraoperatory. Short periods of tachypnea-tachycardia (<1min) were observed, not observed in group B – control during the anesthesia.

Approximately 5 minutes after ligaturing the vessels, the intestinal loops presented hyperperistalsis, afterwards they turned pale.

After approximately 6-7 hours the animal presents respiratory perturbations and death occurs.

Necropsy and histopathological evaluation. The necropsies were effectuated in the scheduled interval of 1-3 hours after death occurred.

While the external examination, the corpses showed the signs of real death. In three of the five cases, the outflow of a serohemorrahic liquid through the suture's fibers was observed.

While opening the abdominal cavity, in three of the five cases from group A, approximate 3 ml serohemorrahic ascites were stated. The cytological examination revealed rarely flaked mesothelial cells, rarely erythrocytes and leukocytes.

Signs of peritonitis were not observed.

The intestine is relaxed, with parietal edema, and thrombosis in the mesenteric vascular arcades (fig. 9).

On the surface, the duodenum presents the color pink-cyanotic and an accentuation of the parietal vascular drawing (fig. 9), the microscope shows the necrosis of the duodenal villosity and stasis is stated (fig. 10).

Concluding that the duodenum presents incipient ischemic modifications.

On the surface, the proximal jejunum presents the color Bordeaux and thrombosis in the adjacent mesenteric vessels. The distal jejunum and the ileum presents strongly cyanosed loops with the color purple-black (fig. 11); the mucosa is intensely red colored. Thrombosis in the adjacent mesenteric vessels is remarked. Microscopically, massive necrosis of the intestinal mucosa and submucosa is stated, necrotic-hemorrhagic content in the lumen. Thrombosis in the mesentery (fig. 12).

On the level of the appendix, no ischemic modifications are stated.

The proximal cecum presents a purple-black color whereas the distal cecum and the proximal colon presents alternations of purple and light grey areas (fig. 9). Microscopically, this segment of the digestive tube presents partial necrosis of the mucosa, areas where the epithelium of the surface is ulcerated, stasis and thrombosis in mucosa, alternating with areas of normal aspects (fig. 13, fig. 14). The distal colon presents incipient ischemic modifications or has a normal aspect.

The mesentery presents a hemorrhagic infiltration.

The liver presents stasis and multiple Zahn infarcts (fig. 15). The spleen presents stasis and thrombosis in the splenic vein (fig. 16). The stomach presents stasis and, in two of the five cases, hemorrhagic shock ulcerations (fig. 17).

The pancreas presents stasis and necrotic areas (fig. 18). The paravertebral ganglia present stasis (fig. 19).

The microscopically control of the ligature reveals the complete halting of the bloody flux in the cranial mesenteric package (fig. 20).

DISCUSSION

The splanchnic circulation receives approximately 25% of the resting and 35% of the postprandial cardiac output (18-19). 70% of the mesenteric blood flow is directed to the mucosa and submucosa of the

bowel, with the remainder supplying the muscularis and serosal layers. Multiple major elements interact to provide the intestinal tract with an appropriate share of the blood supply, including the intrinsic (metabolic and myogenic) and the extrinsic (neural and humoral) regulatory systems (19-20).

Pressure-flow autoregulation, reactive hyperemia, and hypoxic vasodilation are considered intrinsic controls. In the metabolic theory, oxygen delivery rather than blood flow causes adaptive changes in splanchnic circulation. An imbalance between tissue oxygen supply and demand will raise the concentration of local metabolites (hydrogen, potassium, carbon dioxide, and adenosine), resulting in vasodilation and hyperemia. The myogenic theory suggests that arteriolar tension receptors act to regulate vascular resistance in proportion to transmural pressure. An acute decrease in perfusion pressure is compensated for by a reduction in arteriolar wall tension, thereby maintaining splanchnic blood flow (21).

The vascular network of the submucosa prevents the installation of ischemia when the irrigation's debit of the extramural vessels sinks significantly (22).

In the first place, in physiological conditions, only 20% of the mesenteries capillaries are opened; when one of the mesenteric arteries is obstructed, a reduction of pressure takes place in the distal arterial bed, which triggers the opening of the capillaries of submucosa. After a couple of hours, this compensatory mechanism is overstrained and the distal arteries enter vasoconstriction. Initially, the vasoconstriction is reversible, but after a period of time it can become irreversible, even if the trigger of the ischemia was identified and corrected (23).

In the second place, when the O_2 contribution sinks, the extraction capacity grows (once the bloody flux sinks under 30ml/min/100g tissue or the systemic blood pressure drops under 50mmHg, the O_2 extraction becomes dependent on the flux (24)).

In this way, the intestine could endure a sinking of 75% of the irrigation debit up to 12 hours without causing cellular injury (25).

Through the sudden and complete installation of the vascular obstruction during the CMA ligature, the compensatory mechanisms are rapidly overstrained and it cannot be talked about the capacity of collateral circulation. The obtained results of our team are similar to those obtained by experimentally reproducing the mixed infarction in rabbits (the bowel became pale 5 to 10 minutes after vessel ligation, 3 hours after the ligation, the necrosis of the small bowel was evident, 6 hours after the ligation, the animals had extensive patchy necrosis and dilation throughout the small bowel with free hemorrhagic intraperitoneal fluid, 9 hours after the ligation, the small bowel was dilated and black, most of the animals died 9 hours after vessels ligation (26)) or in dogs (30 minutes after ligaturing, the loops are lightly cyanotic, without peristalsis; after 1h the loops are relaxed, Bordeaux colored, with parietal edema, the mesenteric vascular arcades are turgescent, ascites is present; after 1,5 hours the loops are strongly cyanotic, ascites in great amount, after 2,5 hours the loops are black, in some places perforated, the mesentery strongly infiltrated, all the vascular arcades are black, rigid, after 3,5 hours the animal dies (17)).

The fact that the proximal duodenum

and jejunum presents incipient, respectively middle ischemic modifications are due to the anastomotic paths given by the celiac trunk through the right pancreatico-duodenal arteries, which form an anastomosis with the left pancreatico-duodenal, the first collateral of the CMA. The distal colon presents minor or absent ischemic modifications due to the vascularization which gets through the anastomosis of the caudal mesenteric artery with the Riolan arcade and through the collaterals from the caudal mesenteric artery.

The lack of an adequate oxygen supply leads to tissue ischemia, which, in turn, causes cellular dysfunction and cell death (27). Intestinal injury causes significant damage to the intestine, particularly to the mucosa and neurons. The epithelial surface of the mucosa can be lost, which allows bacteria and toxins to enter the gut wall, compromises the ordered absorption of nutrients, and disturbs regulated water and electrolyte transport (28-30). The basic electrical rhythm of the intestine is known to decrease during mesenteric ischemia (31-32).

The most abundant constituents of epithelial cellular membranes are phospholipids. After ischemia, the oxygen radicals, which are the products of this oxidative stress, destroys lipid via lipid peroxidation (33). Consequently, intestinal permeability increases, lysosomal hydrolases are released and proteolysis is enhanced, and intestinal barrier fails through destruction of endothelial and epithelial cells. Finally, indigenous enteric bacteria translocates to extra intestinal sites, induces sepsis and multiple organ system failure (34-37).

On the other hand, 20-25% of the cardiac debit stays sequestrated after ligaturing the mesenteric vessels, thus the animal suffers a volume depletion.

The fact that multiple abdominal organs present stasis, attests the cardio-circulatory insufficiency installed post operatory.

CONCLUSIONS

By ligaturing of the CMA and of the CMV, we obtained an experimental model of the mixed intestinal infarction in rabbits.

Necropsy and histopathological evaluation showed: the duodenum presents incipient ischemic modifications, the distal jejunum and the ileum presents massive necrosis of the mucosa and submucosa, the cecum and the proximal colon presents partial necrosis of the mucosa, areas where the epithelium of the surface is ulcerated, stasis and thrombosis in mucosa, alternating with areas of normal aspects; the distal colon presents incipient ischemic modifications or has a normal aspect.

On the level of the appendix, no ischemic modifications are stated.

The mesentery presents hemorrhagic infiltration.

Multiple abdominal organs present stasis (liver, spleen, sympathetic ganglions) or shock signs (stomach, pancreas).

The rabbits died by the cardio-circulatory insufficiency and multiple organ system failure.

NEWS

A NOVEL ONCE-WEEKLY DPP-4 INHIBITOR IN THE CARE OF TYPE 2 DIABETES

Omarigliptin is a novel onceweekly (q.w.) dipeptidyl peptidase IV (DPP-4) inhibitor for the treatment of patients with type 2 diabetes. This study aimed to evaluate the long-term safety of optimal dose. In a multicenter, double-blind, 12-week, dose-range finding study, 685 oral antihyperglycemic agent-native or washed-out subjects with type 2 diabetes were randomized to one of five once-weekly doses of omarigliptin (0.25 mg, 1 mg, 3 mg, 10 mg, or 25mg) or placebo. Analysis included all patients who received at least one dose of the study medication. At week 12, the omarigliptin 25-mg dose provided the greatest glycemic efficacy. Subjects who completed the base study were eligible to enter a 66-week extension study. Omarigliptin 25 mg q.w., compared with placebo, provided significant glucose lowering and was generally well tolerated throughout the base and for up to 78 weeks in patients with type 2 diabetes (Sheu WHH, Gantz I, Chen M et al. Safety and efficacy of Omarigliptin (MK-3102), a novel once-weekly DPP-4 inhibitor for the treatment of patients with type 2 diabetes. *Diabetes Care.* 2016;38:2106–2114 | DOI: 10.2337/dc15-0109).

EARLY COMPLICATIONS FOLLOWING ANATOMIC LUNG RESECTIONS- EXPERIENCE OF A THORACIC SURGICAL ONCOLOGY UNIT (Abstract). **Aim:** To analyze the medical and socioeconomic impact of the complications of anatomic lung resections performed at the Thoracic Surgery Unit of the Iasi Regional Cancer Institute. **Methods:** This retrospective study included patients who underwent anatomic lung resections between January 2013 and August 2015**. Results**: Over this interval a total of 172 major lung resections were performed: 31 (18.02%) pneumonectomies, 5 (2.91%) bilobectomies, and 136 (79.06%) lobectomies. Complications occurred in 36 patients, including bronchial stump fistula in 7 patients (4.06%), bronchopneumonia (9/5.23%), pleural empyema without bronchoscopically documented bronchial stump fistula (1/0.58%), chylothorax (1/0.58%), postoperative arrhythmia (3/1.74%), early postoperative stroke (1/0.58%), prolonged air leak (requiring hospital stay longer than 14 days) (11/6.38%), and postoperative hemothorax requiring reintervention (3/1.74%). Secondary to complications, a number of 3 (1.74%) patients died early postoperatively. **Conclusions:** The incidence of immediate and early postoperative complications is comparable to those reported by other authors. **Keywords:** ANATOMIC LUNG RESECTIONS, EARLY COMPLICATIONS, LOBECTOMY, BILOBECTOMY, PNEUMONECTOMY.

Lung cancer surgery is associated, according to the literature (1, 2), with a wide range of complications that can occur in the immediate postoperative period. The most frequent are supraventricular arrhythmias, prolonged air leaks, atelectasis of the remaining parenchyma and hemorrhages, while pneumonia, empyema, bronchopleural fistulas, chylothorax, wound complications, lobar torsion and nerve lesions are less common (1, 2). Most of these complications can be treated conservatively, but have an important impact on quality of life and patient survival by prolonging the time interval from surgery to initiation of adjuvant therapy, especially considering the favorable outcomes of neoplastic bronchopulmonary lesions with adjuvant therapy even in elderly patients with good performance status (3).

The paper aims to analyze the medical and socioeconomic impact of immediate complications occurring in patients who have undergone major surgery in the Thoracic Surgery Unit of the IInd Surgical Clinic of the Iasi Regional Cancer Institute.

MATERIAL AND METHODS

This retrospective study was conducted on a group of 172 patients who underwent anatomic lung resections and aimed at conducting an audit of the early complications following this type of resection. The data for this study were collected from the medical records of patients who underwent anatomic lung resections between January 2013 and August 2015 in the Surgery Clinic II of the Iasi Regional Cancer Institute. In this study we used the term anatomic lung resections to define surgeries such as pneumonectomies, bilobectomies and lobectomies.

The data collected from medical records included: gender, area of residence, main and secondary diagnoses, type of surgery performed and histopathology report, reported complication, duration of the surgical procedure, time between surgery and complications and length of hospital stay.

RESULTS

Clinical data. Over the 32 months study interval 172 major lung resections have been performed, of which 31 (18.02%) pneumonectomies, 5 (2.91%) bilobectomies and 136 (79.06%) lobectomies. 36 (20.93%) of these patients experiencing complications: 28 following lobectomies, 7 following pneumonectomies, and 1 following bilobectomy.

The comparative analysis by gender, age, duration of surgery and length of hospital stay between all patients who underwent major lung resections and those who developed complications showed significant differences in incidence (tab. I)

TABLE I

Distribution of patients by sex, age, mean duration of surgery and mean length of hospital stay

Characteristics of the group	Group of patients who underwent anatomic lung resections	Group of patients who experienced complications
Male/female	131/41	32/4
Age (years)	62.52 ± 9.29	62.7 ± 9.46
Length of hospital stay (days)	14.54 ± 8.16	20.27 ± 13.39
Duration of surgery (minutes)	154.1 ± 43.94	163.46 ± 42.95

Histological features. In the subgroup of patients who experienced complications 52.7% underwent surgery for bronchopulmonary adenocarcinoma. The distribution of patients experiencing complications by histological type of the lesion that required surgery showed: 19 (52.7%) adenocarcinomas, 10 (27.77%) squamous cell carcinomas, 2 (5.55%) small cell carcinomas and one case each (2.77%) of neuroendocrine carcinoma, pleomorphic sarcomatoid carcinoma, cystic adenomatoid malformation, bronchogenic cyst and aspergilloma.

Analysis of complications. Analysis of medical records allowed the classification of complications into pleuropulmonary and extrapulmonary (tab. II). In the analyzed study group 3 (1.74%) deaths secondary to complications of major lung resections were recorded. One of these patients required reoperation for hemothorax 3 hours after left pneumonectomy and death occurred as a result of nosocomial pneumonia in the remaining lung. The second death was caused by cardiorespiratory arrest secondary to pneumonia in the remaining parenchyma following right pneumonectomy. The third death was due to respiratory failure unresponsive to therapy following a right superior lobectomy.

TABLE II
Distribution of patients by type of complications

General complications			Pleuropulmonary complications		
No.	*Percentage (%)*	*Complication type*	*No.*	*Percentage (%)*	*Complication type*
3	1.74	arrhythmia	11	6.38	prolonged air leaks
1	0.58	stroke	9	5.23	pneumonia
			7	4.06	bronchial stump fistula
			3	1.74	hemothorax
			1	0.58	empyema without documented bronchial fistula
			1	0.58	chylothorax

DISCUSSION

Analyzing the obtained results, the general complications in the study group included 3 (1.74%) cases with postoperative arrhythmias and 1 (0.58%) patient with postoperative stroke. Comparatively, Mitsudomi et al. (4) reported a rate of postoperative arrhythmias of up to 35%. In our study there were no cases of pulmonary embolism, redoubtable complication of lung resection surgery as indicated in their works by Dent et al. (5) and Ziomek et al. (6).

As to the postoperative pleuropulmonary complications, other authors mention such complications requiring reintervention as hemothorax, bronchial stump fistulas and pleural empyema (7). According to these authors hemothorax is present in 52-75% of cases (8, 9). Currently it is estimated that the rate of hemorrhagic complications of lung resection surgery is of about 3% due to technical progress in the design of surgical instruments and surgical techniques in a multidisciplinary approach context (7). In our study postoperative hemothorax was present in 1.74% of cases.

Bronchial stump fistulas occurred in 7 (4.06%) of our study patients. Three (1.74%) of these 7 cases required reoperation consisting in completion pneumonectomy, repair of the bronchial stump followed by closure of the remaining stump and plasty of the suture using serratus muscle flap. In 4 (2.32%) patients the fistula was closed bronchoscopically with biological glue. Other authors (7, 8, 9) reported the presence of this complications in 17.8% -25.5% of the cases. Pleural empyema without documented bronchopleural fistula was present in 0.58% of the patients in our study, compared with 2-12% reported by Vallieres et al. (10). Lobar torsion was found by Wong et al. in 0.5% of cases (11). In our study no patient developed this complication, the explanation being the fixation of the middle lobe to the inferior lobe after all right upper lobectomies.

Prolonged air leaks, reported by other authors as a frequent problem with an incidence of up to 50% of patients (10) were found in 6.38% of our study patients. Along with bronchial stump fistulas they are associated with a significant increase in length of hospital stay with important economic implications, explaining the particular interest of other studies describing the development of predictive scores for persistent air leaks, such as IPAL (Index of Prolonged Air Leak) (10). A particular case in our study and rarely reported by other authors (12, 13, 14) was the occurrence of chylothorax following the surgical treat-

ment of a Stocker type II cystic adenomatoid malformation.

The mean length of hospital stay in the group of patients with complications was about 5 days longer compared to the entire cohort of patients, demonstrating the negative impact of delayed initiation of adjuvant therapy on patient survival. The difference of about 10 minutes between the average duration of surgery for the entire study group and for the patients with complications suggests a possible relationship between case difficulty and complications.

CONCLUSIONS

Our findings on immediate and early complications after major lung resections are comparable to those in the literature. The impact of these complications on the quality of life and survival of patients due to the delayed initiation of adjuvant therapy remains a topic of major interest, and the periodic follow-up data of the patients in the study will be published later.

CONCENTRATIONS OF VITREAL CYTOKINES IN RHEGMATOGENOUS RETINAL DETACHMENT (Abstract): Proliferative vitreoretinopathy (PVR) is one of the most frequent causes of failure of rhegmatogenous retinal detachment (RRD) surgery. **Aim:** To measure the vitreous levels of granulocyte colony stimulating factor (G-CSF) and monocyte chemoattractant protein 1 (MCP-1) in eyes with RRD and in a control group. **Material and methods:** A prospective study of 40 patients operated for RRD (study group) and 20 patients with epiretinal membrane or macular holes (selected as control group since they needed vitrectomy but had attached retinas). Vitreous samples were collected during vitrectomy and were assessed for the presence of cytokines using a fluorescent bead-based multiplex assay. **Results:** The concentration of G-CSF (8.59 pg/ml) and MCP-1 (1615.2 pg/ml) were significantly increased in the study group, when compared to the control group (0 and 469.13 pg/ml, respectively). MCP-1 was also significantly increased in the subgroup of patients with PVR compared to the patients with uncomplicated RRD. **Conclusions:** The levels of these biomarkers support the idea that proliferative vitreoretinopathy has an inflammatory component. **Keywords:** RHEGMATOGENOUS RETINAL DETACHMENT, PROLIFERATIVE VITREORETINOPATHY, VITREOUS CYTOKINES.

INTRODUCTION

Proliferative vitreoretinopathy (PVR) is a complication of rhegmatogenous retinal detachment (RRD) characterized by fibrocellular, contractile, epiretinal or subretinal membranes that prevent retinal reattachment. It is one of the most frequent causes of RRD surgery failure (1). Retinal break and subsequent retinal detachment are believed to allow macrophages, retinal pigment epithelial cells, glial cells and fibroblasts to migrate into the vitreous, where they proliferate, form extracellular matrix and assemble into membranes (2).

Several models of the pathogenesis of this disease have been described, some models focusing on the role of inflammatory cells, others on the role of growth factors and cytokines (2). Numerous authors have identified elevated levels of a variety of growth factors, cytokines and chemokines in the vitreous of eyes with PVR (3).

Cytokines serve as signals between cells and are involved in cell proliferation and

migration, inflammation, angiogenesis and fibrosis. Chemokines are mediators that may promote recruitment of leukocytes to the sites of inflammation, enhance immune responses, and also participate in angiogenesis and fibrosis (4).

Multiplex bead-based flow cytometric assays have the major advantage of assessing the presence of numerous different biomarkers in a small quantity of biological fluid. Several authors believe that multiplex immunoassays show similar performance to ELISA in terms of accuracy and reproducibility and have superior sensitivity. (5).

In the present study we have measured the vitreous concentrations of granulocyte colony stimulating factor (G-CSF) and monocyte chemoattractant protein-1 (MCP-1) in eyes with RRD and in a control group, using a multiplex fluorescent bead-based flow cytometric assay.

MATERIAL AND METHODS

The design of this study was prospective, controlled and observational. The study group consisted of 40 eyes of 40 patients with RRD who underwent 23-G pars plana vitrectomy in the Ophthalmology Department of the Iasi University Hospital, Romania, between March and September 2015. All patients were aged over 18 years and had a primary RRD. There were 30 patients with uncomplicated RD and 10 patients with RD and PVR (4 stage B, 5 stage C and 1 stage D, according to the 1983 Retina Society classification) (6). The exclusion criteria were: history of intraocular surgery in the past 6 months, history of intraocular inflammation, diabetic retinopathy or retinal vascular occlusions, general or intraocular steroids or anti-vascular endothelial growth factor in the past 3 months, impossibility to visualize the causative retinal break preoperatively.

The control group consisted of 20 patients with macular hole or epiretinal membrane who also underwent pars plana vitrectomy. We have selected these conditions because the retinas are attached but they also require a surgical approach, thus providing an opportunity for the sampling of vitreous.

All patients and controls underwent an ophthalmological examination by the recruiting surgeon, including measurement of visual acuity and intraocular pressure, biomicroscopy of the anterior segment of the eye, biomicroscopy or indirect ophthalmoscopy of the posterior segment.

The study was conducted according to the principles of the Declaration of Helsinki and was approved by the Ethics Committee of the Iasi University of Medicine and Pharmacy. Informed consent was obtained from each patient prior to study initiation.

Surgeries were performed by a single surgeon (C.D.), using local anesthesia, 3-port transconjunctival vitrectomy system (Alcon Constellation, Alcon Laboratories, Alcon, Fort Worth, Texas, USA) and a wide-angle viewing system (EIBOS, Moeller-Wedel GmbH & Co. KG, Wedel, Germany).

The vitreous samples were obtained undiluted by manual suction in a sterile syringe connected to the vitreous cutter, before opening the infusion line. If suction became impossible because of blocking with vitreous gel, the cutter function was activated and the suction continued. The content of the syringe was immediately transferred into labelled 1.5 ml Eppendorf Protein LoBind tubes and frozen at -20° C. The tubes were then stored at -150° C. In all cases, the infusion line was opened

immediately after sample collection and vitrectomy was carried on uneventfully.

All vitreous samples were thawed and centrifuged in September 2015. The concentrations of biomarkers (cytokines, chemokines and growth factors) were measured using a multiplex microbead-based immunoassay designed for cytometry. (Cytometric Bead Array®, BD Biosciences, New Jersey, USA). The capture beads corresponding to each analyte to be measured were mixed together in wash buffer, centrifuged, the supernatant was discarded and the beads were resuspended in diluent to a final concentration of 50 µl/test. 50 µl of the supernatant from the centrifuged samples were incubated in labelled tubes with 50 µl mixed capture beads for 1 hour at room temperature. 50 µl of phycoerythrin (PE) detection reagent were added in each tube and then incubated for 2 hours. After washing away the unbound PE and resuspension in wash buffer, the samples were acquired on a FACSAria™ flow cytometer platform. Each bead population has distinct fluorescence intensity, permitting simultaneous measurements of multiple protein concentrations. The median fluorescence intensity of each biomarker was correlated with the dilution of standard biomarkers, the resulting correlation enabling us to quantify the concentration of biomarkers in the study samples. The sensitivity range of each assay was 0-2500 pg/ml.

The statistical analysis was performed using MedCalc (MedCalc Software bvba, Ostend, Belgium). The significance of the difference in concentration of biomarkers between groups was assessed by the Wilcoxon test. A p value of less than 0.05 was considered significant.

RESULTS

The mean granulocyte colony stimulating factor (G-CSF) concentration in the study group was 8.59 ± 28.9 pg/ml (between 0-161.9 pg/ml), whereas all thye eyes in the control group had undetectable levels of G-CSF (0 pg/ml). Since the found values did not have normal distribution, a Wilcoxon test was used to study the difference between groups. The difference was statistically significant, p=0.02.

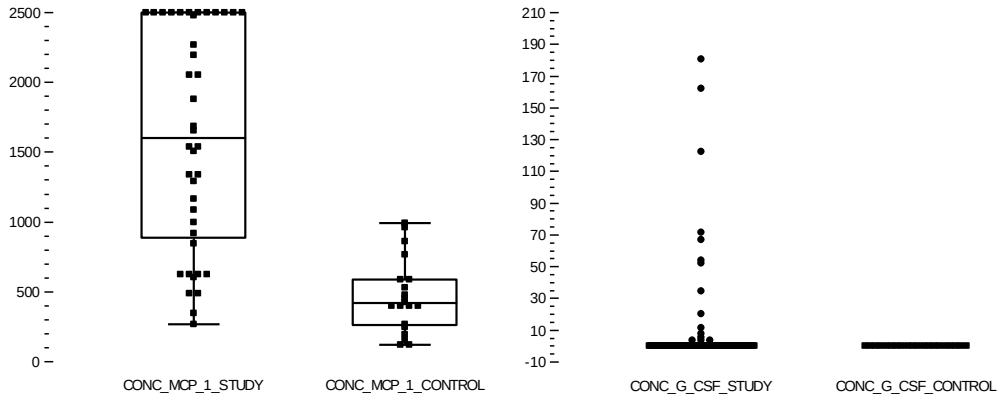

Fig 1. Concentrations of cytokines in the study and control group (pg/ml)

The mean monocyte chemoattractant protein-1 (MCP-1) concentrations in the study and control group were 1615.2 ± 790.8 pg/ml (range 270.1- 2500) and 469.13 ± 263.08 pg/ml (range 118.48-990.49), respectively. The Wilcoxon test showed a highly significant difference, p=0.0001 (fig. 1).

When comparing the concentrations of MCP-1 and G-CSF between the PVR and non-PVR group we found a significant increase of MCP-1 in the PVR group (but not of G-CSF). (tab. I)

TABLE I

Concentration of G-CSG and MCP-1 in retinal detachment – comparison between eyes with or without proliferative vitreoretinopathy.

	Mean concentration, RRD without PVR (pg/ml)	Mean concentration, RRD with PVR (pg/ml)	Wilcoxon test p value
G-CSF	4.09 ± 14.31 (0-71)	22.12 ± 51.92 (0-161.9)	0.6
MCP-1	1451.22 ± 795.15 (270.16-2500)	2107.46 ± 560.4 (597.3-2500)	0.029

DISCUSSION

The course of PVR is the result of the balance (or disruption of balance) between the destructive and protective mechanisms triggered by the occurrence of a retinal break.

The clinical features of PVR corresponds to the histopathological findings, represented by fibrocellular (and, in evolution, contractile) membranes on the anterior or posterior retinal surface (3).

The primordial element seems to be partial de-differentiation, migration and proliferation of retinal pigment epithelial (RPE) cells, creating areas of hyperplasia, first at the limit between detached and attached retina and at the margins of retinal breaks. This process may start 3 days after retinal detachment begins. The next step is the activation of glial cells, with proliferation of astrocytes, Muller cells, microglia and capillary endothelial cells (1).

The role of growth factors, cytokines and chemokines is highlighted by an ever-growing body of literature, the sampling of vitreous and subretinal fluid being relatively easy during modern vitreoretinal surgery. The measuring of different factors is also made easier by tests that use minute quantities of biological material.

In our study group of eyes with rhegmatogenous retinal detachments we found a significant increase in the concentrations of G-CSF and MCP-1 (when compared with a control group of eyes with macular holes or idiopathic epiretinal membranes).

Our findings support the data published by Kunikata et al. (8) who have also found that MCP-1/CCL2 and G-CSF were significantly elevated in eyes with RRD, while TNF was not. They have reported that intravitreal triamcinolone is able to suppress elevated levels of intraocular MCP-1 in eyes with RRD. MCP-MCP-1 (also known as C-C motif ligand 2) is a chemokine that recruits monocytes, memory T cells and dendritic cells to sites of tissue injury (4). In animal models of retinal detachment, it is expressed in the Muller glia and macrophage/microglia. It may contribute to monocyte recruitment in areas of RRD, and appears to be implicated in the pathogenesis of photoreceptor degeneration and apoptosis following retinal detachment (9).

Yoshimura et al. (4) have also reported that MCP-1 was significantly elevated in

eyes with diabetic macular edema, proliferative diabetic retinopathy, vein occlusion or rhegmatogenous retinal detachment. They have found that MCP-1, IL6 as well as IL8 are increased.

G-CSF is a cytokine that stimulates the survival, proliferation and function of neutrophil precursors and mature neutrophils. In an experimental setting, vitreous from eyes with proliferative vitreoretinopathy stimulated G-CSF and IL-17A production by ARPE-19 cells (10). G-CSF has been shown to have a neuroprotective effect after retinal ganglion cell axotomy (11)

In a retrospective case-control study, Ricker et al. (12) have compared the concentration of 50 biomarkers in the vitreous of patients with uncomplicated RRD and patients who developed PVR within the first 3 months after surgery. They have found a significant increase of IL2, MCP-1/CCl2 and other 15 biomarkers in the vitreous of patients that developed PVR. They found no differences for the values of IL4, IL10, IL12p70, VEGF, bFGF, TNF and other 17 biomarkers (however, they did not provide values for the biomarkers that did not differ between the study and control group). Banerjee et al. (13) promoted the idea that the detectable levels of interleukins and chemokines support the role of an inflammatory response in PVR.

CONCLUSIONS

In our study group of patients with rhegmatogenous retinal detachment, the concentrations of G-CSF and MCP-1/ CCL2 are significantly increased when compared with a control group. A significant increase of MCP-1 in eyes with proliferative vitreoretinopathy compared to eyes with uncomplicated retinal detachments was also found, supporting the hypothesis of the implication of this soluble factor in the pathogeny of PVR.

DREAM OR REALITY? VIDEO HEAD IMPULSE TEST READY TO BE USED

Looking in the past, over the history of vestibulogy, the aim was always to measure the function of all the vestibular receptors. Vestibular evoked miogenic potentials (cervical and ocular) show the activity of the saccule and the utricle. Now, using video Head Impulse Test is possible quantify the semicircular canals function by measuring the eye rotation response to an abrupt head rotation in the plane of the canal. The main measure of canal adequacy is the ratio of the eye movement response to the head movement stimulus i.e. the gain of the vestibulo-ocular reflex (VOR). However there is a need for normative data about how VOR gain is affected by age and also by head velocity, to allow the response of any particular patient to be compared to response of healthy subjects in their age range. This study held on helthy subjects divided in decade age groups. VOR gain decreased at high head velocities, but was largely unaffected by age (McGarvie LA, MacDougall HG, Halmagyi GM, Burgess AM, Weber KP, Curthoys IS. The Video Head Impulse Test (vHIT) of Semicircular Canal Function – Age-Dependent Normative Values of VOR Gain in Healthy Subjects. *Frontiers in Neurology* 07/2015; 6:154.)

VACCINATION – COLLECTIVE RESPONSIBILITY OR VIOLATION OF RIGHTS? (Abstract) Vaccination is considered to be the most effective and the cheapest medical intervention through which individual and collective immunisation is achieved. Statistics show that, at present, immunisation annually saves 400 million lives and protects approximately 750,000 children against disabilities of varying degrees. Approximately 80% of worldwide children are vaccinated against diphtheria, tetanus, pertussis, polio, measles, etc.; these diseases used to be considered incurable in the past. Vaccines help the body to produce antibodies; they help the immune system to detect germs and inactivate their cells. The immunological protection is installed after a variable period of time following the inoculation and is long lasting. Immunisations can be achieved in several ways: through national immunisation campaigns with general recommendation – they may be compulsory, optional or prophylactic (for the diseases for which a vaccine is available); vaccinations not included in the compulsory immunisation programmes; they may also be targeted to the contagious infectious outbreaks or to groups of population in certain situations. There is no guarantee that a vaccine will provide 100% protection. However, it will significantly reduce the risk of getting an infection. Vaccines have side effects which can be divided into reactions triggered by the vaccine or reactions exacerbated by it, without a causal relationship to the vaccine. **Keywords**: VACCINE, IMMUNISATION, BCG, VPI.

According to a survey conducted in March this year, one in ten Romanians has no confidence in vaccinations, and one in three is uncertain about immunisation. Despite the statistics, vaccination still remains, according to experts, the most important means of preventing diseases, particularly those with an epidemic evolution (1).

Throughout the world history, there have been laws which imposed immunisations on people and, at the same time, social movements which opposed them. Such examples can be found Britain, where the Vaccination Act of 1853 made the vaccina-

tion against smallpox compulsory for children aged up to 3 months. Later, in 1867, the law was changed and the vaccination against smallpox became compulsory for children under 14 years old. Over time, people have objected to vaccines in multiple ways. Firstly, they were bothered by the mandatory character of immunisations, as they considered it as a human rights violation (1, 2). The Leicester Demonstration March of 1885 defines the anti-vaccination movement of those years. Almost 100,000 people went out in the streets with banners and branded dolls of Edward Jenner. All these movements shortly led to the establishment of the first British commission to study the impact of vaccination on the public health. In 1896, the Commission concluded that the vaccine was effective against smallpox. At the same time, however, the same commission suggested removing sanctions for non-vaccination (2).

In 1905, the US Supreme Court ruled that states were entitled to coerce vaccination to protect its citizens in case of infectious diseases. It was the first decision of the Supreme Court related to the issue of public health. Today, in Belgium, parents who do not vaccinate their children against polio are fined and sentenced to up to five months in prison. In Australia, parents and GPs receive material rewards for vaccination. In the UK, material rewards are given to doctors only when they achieve the immunisation targets set by the government (2).

HISTORY

Vaccination is a means of prophylactic active immunisation against diseases by inoculating a biological formula with antigenic properties, which triggers the occurrence of an immune response in the body subject to vaccination. Immunological protection is installed after a variable period of time after inoculation (weeks, months), depending on the vaccine, and is active for a long period of time (years). Some vaccines are administered in maternity, while others are administered soon after birth. Using special techniques, harmful components that can trigger the disease mechanism are removed from the extremely complex structure of the virus, and only structures useful for stimulating the immune response are used (2).

Edward Jenner, the one who gave the name of "vaccine" to the immunisation process, noticed that patients who developed cowpox (an infectious disease specific to cows that is transmissible to humans and is characterised by cutaneous rash) were protected against smallpox. A cowpox epidemic outbreak on a farm in the spring of 1796 gave him the opportunity to experiment and to broaden his knowledge and research. In May 1796, he made an incision on an 8-year-old boy's arm, where he applied pus collected from a pustule of a milkmaid infected with cowpox. A pustule appeared at the incision site, which healed shortly thereafter. In July 1796, Jenner voluntarily and consciously infected this boy with smallpox, but it turned out that the child was immune to the disease. This made the doctor repeat the procedure on 8 more children, including his son. In all cases, it turned out that patients had become immune to smallpox. Jenner gave the name of "vaccine" to the process, a word derived from the Latin "*vacca*" – cow, and the method was going to expand rapidly in Europe and beyond (3).

IMPORTANCE

Poliomyelitis

Vaccination is considered the most ef-

fective and the cheapest medical intervention, through which the individual and collective immunisation is achieved, which prevents the pathogen from spreading. Statistics show that, at present, immunisation annually saves 400 million lives and protects approximately 750,000 children against disabilities of varying degrees. Also, approximately 80% of worldwide children are vaccinated against diphtheria, tetanus, pertussis, polio, measles, etc.; these diseases used to be considered incurable in the past (2, 3).Vaccines help the body produce antibodies; they help the immune system to detect germs and inactivate their cells. The immunological protection is installed after a variable period of time following the inoculation and is long lasting (years). Immunisations can be achieved in several ways: 1) through national immunisation campaigns with general recommendation – they may be compulsory, optional, prophylactic (for the diseases for which a vaccine is available); 2) optionally, for the prevention of diseases for which a vaccine is available – these vaccines are not included in the compulsory immunisation programmes; 3) they may also be targeted to specific contagious infectious outbreaks or to groups of population in certain situations (2, 4). There is no guarantee that a vaccine will provide 100% protection, but it can significantly reduce the risk of getting an infection. Over time, there have been people who were vaccinated but developed the infection that should have been prevented by the vaccine; yet, it is considered that immunisations used at present do not trigger the disease they are supposed to prevent. Vaccines have side effects which can be divided into reactions triggered by the vaccine, connected to the properties of the vaccine and to the individual response of the body, and which are unlikely to occur in the absence of the vaccine; on the other hand, there are reactions exacerbated by the vaccination, which are present in the absence of the vaccine, but which are enhanced by the vaccination or by manufacturing errors and which have no causal relationship to the vaccine (2, 5).

In Romania, vaccine production began in July 1921 when the government established by decree of King Ferdinand I the Serums and Vaccines Institute, the current Cantacuzino Institute. An important role was played by scientist Ioan Cantacuzino, who prepared the serum anti-dysenteric, the anti-cholera serum, the anti-tetanus serum, the anti-typhoid serum and other serums in the institution he founded and due to which, in our country, many extensive campaigns aiming to eradicate contagious diseases have been conducted. The specialists of the Institute have been in charge of diagnosis, research, public health and education ever since its establishment (2, 4).

The first outbreak was reported in Europe in the early 19th century and in the US in 1843. In the next 100 years there were polio epidemics recorded in the developed countries in the northern hemisphere every summer and autumn. They became increasingly serious and the average age of the people affected increased. Polio reached a very high threshold in the United States in 1952, with over 21,000 cases of paralysis. After the introduction of vaccines, the incidence of polio decreased abruptly. The last case of wild polio virus in the United States was recorded in 1979. In the next 10 years, polio was globally eradicated. A polio eradication programme conducted by the Pan American Health Organization managed to eliminate polio in the Western Hemisphere in 1991 (3, 6).

At a worldwide level, the effort of eradicating polio has taken significant steps since the launch of the Global Polio Eradication Initiative in 1988. At that time, about 350,000 children became paralyzed every year. In 2008, there were only 1,655 reported cases of confirmed polio in the world. In the last 25 years, the number of cases has been reduced by more than 97%; consequently, in 2013 there were 223 cases of polio, which was endemic in only three countries: Afghanistan, Nigeria and Pakistan. In 2013, there was another major epidemic with 174 victims in Somalia (5, 6, 7).

In Romania, there were several epidemic episodes: in 1927, 1955, 1980 – 1982 (221 cases caused by wild polio virus type 2 and 3), as well as between November 11, 1990 – April 25, 1992 (13 cases caused by wild polio virus type 1, which involved unvaccinated children, especially Rrom children, many of them being also infected with the human immunodeficiency virus HIV). WHO official reports show that our country recorded 18 cases in 1992. For the following years, the figures are as follows: 1993 – 10 cases, 1994 – 8 cases and 1995 – 5 cases. 1995 was the last year when our country recorded cases of polio (2, 7, 8).

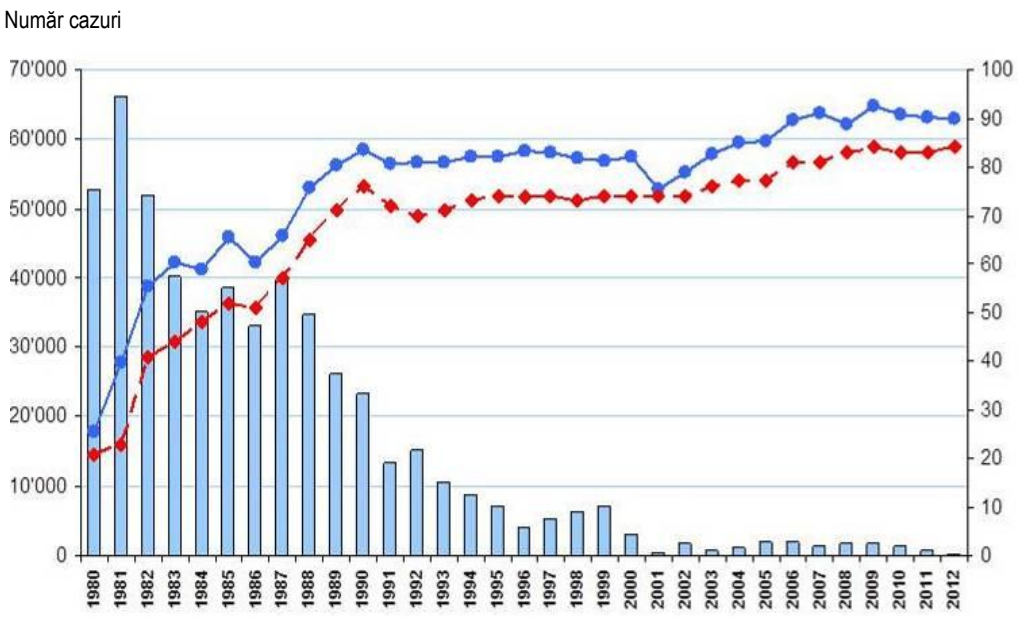

Fig. 1. Number of worldwide annual cases of polio and official immunisation rate / WHO/UNICEF estimates (July, 2013). *Source*: WHO

In Romania, two types of vaccines have been available and used. One of them is the inactivated polio vaccine (IPV) – the first polio vaccine, recorded in 1955 in the US. The second one is the oral polio vaccine (OPV), approved in 1961 as a monovalent vaccine and in 1963 as a trivalent polio vaccine. After the introduction of the OPV vaccination at a global scale, the cases of polio associated to the vaccination (VAPP) started to occur. The World Health Organization concluded, with regard to the safety

of the polio oral vaccine, that there were 1,003 cases of paralysis associated with polio vaccination (VAPP) reported in 13 countries during 1970-1984, out of which 470 cases (47%) were recorded in Romania. After 1995, with the introduction of IPV in the immunisation of children in orphanages and the wide access to oral antibiotics, the incidence of vaccine-associated polio cases has reduced to a case / year on average; in other words, the risk is comparable to that found in other regions where polio immunisation is almost exclusively done with OPV (2, 3, 9).

Inactivated polio vaccine (IPV) is highly effective in producing immunity to polio virus and protection against paralytic forms. Over 90% of vaccinated individuals develop antibodies against all three types of polio virus after two doses and at least 99% are immune after the following three doses. Protection against paralytic polio correlates with the presence of antibodies (6, 7).

IPV produces less local gastrointestinal immunity than OPV, thus the individuals who receive IPV are more easily infected with the wild polio virus than those who are vaccinated with OPV. The duration of immunity following the IPV vaccination is not known with certainty, although the vaccine is likely to provide protection for many years after a full series of vaccinations has been completed (2, 7, 8).

Oral polio vaccine (OPV) is highly effective in producing immunity against the polio virus. A single dose of OPV produces immunity to all three viruses in the vaccine in approximately 50% of vaccinated individuals. Three doses of vaccine develop immunity to all three types of polio virus in 95% of vaccinated subjects. As with other live virus vaccines, the immunity obtained following the vaccination with an oral polio vaccine is expected to last a lifetime. OPV produces excellent intestinal immunity, which helps to prevent infection with a wild virus (6, 7).

Inactivated polio vaccine (IPV) is highly effective in producing immunity to polio virus and ensuring protection against paralytic polio. Over 90% of vaccinated individuals develop antibodies against all three types of polio virus after two doses and at least 99% are immune after the following three doses. Protection against paralytic polio correlates with the presence of antibodies (8, 9). IPV produces less local gastrointestinal immunity than OPV, thus the individuals who receive IPV are more easily infected with the wild polio virus than those who are vaccinated with OPV (7, 9). The duration of immunity following the IPV vaccination is not known with certainty, although the vaccine is likely to provide protection for many years after a full series of vaccinations has been completed.

Oral polio vaccine (OPV) is highly effective in producing immunity against the polio virus. A single dose of OPV produces immunity to all three viruses in the vaccine in approximately 50% of vaccinated individuals. Three doses of vaccine develop immunity to all three types of polio virus in 95% of vaccinated subjects. As with other live virus vaccines, the immunity obtained following the vaccination with an oral polio vaccine is expected to last a lifetime. OPV produces excellent intestinal immunity, which helps prevent infection with a wild virus (8, 9). Serological studies have shown that seroconversion after three doses of IPV or OPV is nearly 100% in all three viruses in the vaccine. However, seroconversion rates after three doses of combined IPV and OPV are lower, especially in the

type 3 vaccine virus (up to 85% in one study). A fourth dose – most studies use OPV for the fourth dose – usually produces seroconversion rates similar to those of the three doses of IPV or OPV (2, 7, 9). OPV trivalent vaccine was chosen in the United States (and in most countries) on its approval in 1963. The almost exclusive use of OPV has eliminated wild polio virus in the United States in less than 20 years. However, with every 2-3 million doses of OPV administered, there is a case of VAPP (vaccine-associated paralytic poliomyelitis), which has resulted in about 10 cases of VAPP in the US every year. In the period 1980-1999, VAPP was responsible for 95% of reported cases of paralytic polio in the United States. In 1996, an increase in the use of IPV was recommended, as part of an IPV/OPV sequential immunization schedule. This recommendation was intended to reduce the occurrence of paralytic polio associated with the vaccine (8, 9, 10). The sequential programme was intended to eliminate VAPP in vaccinated people as a result of the production of humoral immunity to the polio viruses in the vaccine with inactivated polio vaccine administered prior to the exposure to the live virus in the vaccine (2, 5, 9). As VPO was still used for the third and fourth dose in the polio vaccination programme, the risk of VAPP continued to exist among the close contacts of the vaccinated individuals, who were exposed to the vaccine live virus in the stool of the vaccinated people. The IPV/OPV sequential immunization schedule was widely accepted both by suppliers and by parents. In 1998 and 1999, fewer cases of VAPP were reported, proving the result of the increased usage of VPI. However, only a complete elimination of the OPV will lead to the elimination of VAPP. To emphasize the goal of completely eliminating the paralytic polio in the United States, ACIP recommended in July 1999 that inactivated polio vaccine be used exclusively in the United States starting from 2000. OPV is no longer available in the US in routine programmes. The exclusive use of IPV prevented the vaccine live virus from spreading as well as the occurrence of any case of indigenous VAPP (7, 9, 10).

Tuberculosis

According to estimates, one third of the world population is infected with *M. tuberculosis*, and about 90% of infected people show latent asymptomatic infections; in their case, there is a 10% probability that during their lifetime, latent infection might progress to the stage of active tuberculosis (4, 8).

In 2007, 13.7 million chronic active cases were estimated worldwide. In 2010, nearly 8.8 million new cases were recorded as well as 1.5 million TB-related deaths, of which a fourth in patients also infected with HIV, mostly in countries in course of development. It is believed that the number of new cases of tuberculosis worldwide has been declining since 2002. Approximately 80% of the population of Asian and African countries test positive in tuberculin, compared to 10% of the US population. However, in developing countries, many people contract tuberculosis because of low immunity levels, in many cases as a side effect of HIV infection (2, 4).

The only available vaccine is BCG, which is effective against the spread of the disease in childhood, but with a varying degree of protection against pulmonary tuberculosis (therefore controversial). Despite this, over 90% of children are still vaccinated with BCG. Vaccination at an

early age provides immunisation for a period of about 10 years, but cases have been reported where false positive results were determined in the tuberculin skin test, which makes the test unreliable in identifying the disease (2, 11).

It has been shown that the effectiveness of BCG varies geographically. Thus, in India and Malawi it is not effective against tuberculosis (although it helps against leprosy) – the average efficiency is 50% and deaths are reduced by 70%; the protection against TB and miliary (disseminated) meningitis is 75-86%; the protection against pneumonia is 40%; the protection against febrile diseases is 18%. The protective effect lasts for at least 15 years. In many cases, it is assumed that the BCG vaccine alone is enough, and that a second vaccination does not provide extra protection (11, 12).

Tuberculosis occurs more frequently in Romania than in other European countries – the 6th position, according to a WHO ranking of reporting European countries – over 27,000 patients are treated annually for TB, of which more than 15,000 are new cases. It is estimated that an average of 130 cases occur per 100,000 inhabitants, compared to the European average of 30 patients per hundred thousand inhabitants. Of the 15,000 patients diagnosed with tuberculosis annually, 2,000 are relapses, and more than 500 cases develop a severe form, unresponsive to conventional therapy. A national strategy for TB control was drafted in Romania for the period 2015 - 2020, which aims at eliminating TB as a public health problem in Romania by 2020; in other words, TB incidence must decrease by 10% annually during this period (2).

The legal principles of public health assistance are: society's responsibility for public health; focus on population groups and primary prevention; concern for health determinants: social, environmental, behavioural and health services; multidisciplinary and intersectoral approach; active partnership with the population and with central and local public authorities; decisions based on the best scientific evidence available at the time (evidence-based public health); under specific conditions, fundamental decisions based on the precautionary principle (1,2).

CONCLUSIONS

The most important roles of public health care refers to: developing policies, strategies and programmes regarding public health; monitoring and analysing the health of the population; public health planning; epidemiological surveillance, disease prevention and control; strategic management and marketing of public health services; prevention of epidemics, including the establishment of epidemiological state of alertness; protecting the population against environmental risks; informing, educating and communicating to promote health; ensuring the means for responding to disasters or threats to life and health, including the introduction of restrictions on the movement of people and goods (2, 12).

The main areas of intervention of public health assistance are: prevention, surveillance and control of transmissible and non-transmissible diseases by: providing immunisations; control of epidemics; disease surveillance; surveillance of behavioural risk factors; accident prevention; health monitoring, evaluation of the needs of the population in terms of public health services; health promotion and health education by information-education-communication campaigns (1, 2).

In this context, another important aspect needs to be emphasised – the close connection between the right to health and other fundamental rights: the right to life and physical and mental integrity; the right to respect for private and family life; the right to information and the right to a healthy environment.

BILATERAL DACRYOCYSTOCELE CONDUCT AND PRENATAL DIAGNOSIS (Abstract): Dacryocystocele develops during fetal life as a result of the obstruction of the nasolacrimal canal. The disease can be both unilateral and, very seldom, bilateral and it is characterized by the appearance of a cystic blue mass over the area of the lacrimal sac after birth. Prenatal ultrasonography can diagnose dacryocystocele and differentiate between dacryocystocele and other birth defects. We are describing a case of bilateral dacryocystocele observed at 34 weeks of gestation, clearly visualized using 2D ultrasonography. It is very important for the mother to be informed about the treatment, evolution and the potential complications of the disease. It is also necessary to reconfirm the fact that dacryocystocele is not a facial malformation, which could be a major cause of concern and distress for the mother before birth. **Keywords:** Bilaterale dacryocystocele, prenatal diagnosis, treatment.

Dacryocystocele (mucocele, amniocele) is the occlusion of lacrimal drainage system distally and proximally during the fetal life (1).When the lacrimal sac is filled with mucus it is called mucocele, when it is filled with amnion it is called an amniocele (2, 3). The valve of Hasner is the most frequent site of a distal obstruction due to incomplete canalization, a process that starts in the third fetal month and is completed by the sixth month (4, 5). A congenital dacryocystocele accompanies nasolacrimal duct obstruction in approximately 0.1% of infants (6).

The median age of presentation is approximately 7 days of life and it is frequently unilateral in 60% (7) - 100% (5,8-11) but may also be bilateral (12).

Clinically speaking, it appears as a bluish cystic mass located below the medial canthus. Prenatal diagnosis is important because bilateral dacryocystocele extend-

ing intranasally may cause neonatal nasal obstruction (1, 13, 14). Prenatal ultrasound can differentiate dacryocystocele from other birth defects, thus being essential in the early diagnosis, starting from 24 weeks'gestation (15-18).

CASE REPORT

We describe a case of bilateral dacryocystocele seen at 34 weeks of gestation, with clear visualization of this defect using 2D ultrasonography. Examination revealed a two hypoechogenic cystic mass (1 cm), located medially to the eye sockets (fig.1, 2). No anomalies of the intracranial or facial bony structures were found. The amniotic fluid volume was normal for 34 weeks gestation and the orbits appeared symmetrical. Postpartum examination revealed two bluish masses in the left and right medial canthus. The bilateral cyst drained spontaneously three days after birth.

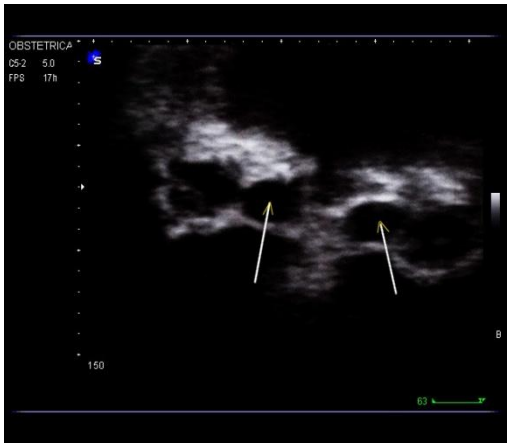

Fig. 1. Ultrasonography-transversal axial section that shows bilateral dacryocystocele (arrows) (Personal collection of PhD A. Cărăuleanu)

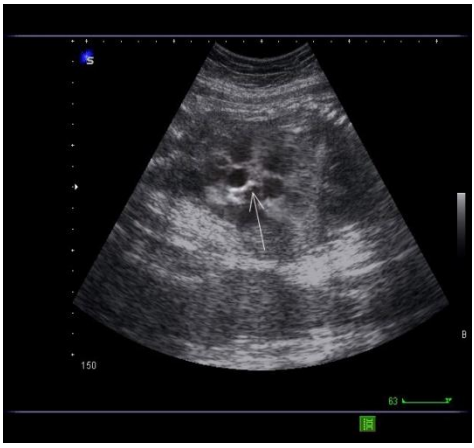

Fig. 2. Ultrasonography-frontal section that shows bilateral dacryocystocele (arrow) (Personal collection of PhD A.Cărăuleanu)

Prenatal diagnosis of dacryocystocele is simple due to its specific appearance and position.

Diagnostic tests: Routine obstetrical ultrasound may identify a specific hypoechogenic mass located inferomedially to the orbit. If this diagnosis is not set before birth, physical examination can provide enough evidence for its recognition, after birth (1, 5).

Associated anomalies:

- no associated anomalies are usually present, but the cyst may cause septal deviation
- the occurrence of hyperteleorism is rarely, due to the extra soft tissue at eye level.

Differential diagnosis includes:

- meningo-encephalocele (11)
- hemangioma
- dermoid cyst
- nasal glioma (2).

Prognosis: excellent, dacryocystocele being a benign tumor, there is no predisposition to developing a facial anomaly. Once corrected spontaneously, medically or surgically the infant will have a normally

functioning nasolacrimal drainage system.

Management:

- it can resolve spontaneously
- external digital pressure on the cyst may allow the contents to decompress through the nose
- if conservative treatment fails, probing of the nasolacrimal duct is performed
- recurrence is possible following probing the nasolacrimal duct
- rarely dacryocystorhinostomy may be required.

DISCUSSION

Congenital dacryocystocele is relatively common in newborns and infants (19). This clinical entity is a congenital obstruction of the nasolacrimal duct resulting from the upper obstruction of the Rosenmuller valve and lower obstruction of the Hasner valve, and it usually develops in first weeks after birth (2, 4, 11, 20, 21).

The frequency of congenital dacryocystocele reported by different authors ranges from 1.25% to 12.5% (22). Numerous studies have shown that this disease is more common in women because they have a narrower nasolacrimal duct than men (23). The mechanism for dacryocystocele formation is represented by the filling of the lacrimal system with mucoid secretions, amniotic fluid, tears and bacterial colonization (19) resulting in the distension of the lacrimal system and occurrence of a bluish cystic formation located upper and below the medial canthus.

Fig. 3. Normal anatomy compared to dacryocystocele (After Tardiff A, *et al*.,1991) (24)

The correct diagnosis of this clinical entity is important as it can often be mistaken for an encephalocele, hemangioma, dermoid or sebaceous cyst (23).

Dacryocystocele can be diagnosed prenatally by ultrasound scanning, which is a non-invasive method, and can be confirmed after birth by CT, MRI and surgical maneuvers for probing the nasolacrimal duct.

Rand (1989) (25) and Walsh (1994) (26) diagnosed dacryocystocele by ultrasound scanning at 30-36 weeks gestation.

Sharony *et al*. (1999) (27) reported an early diagnosis at 27 weeks gestation, describing 6 cases of dacryocystocele. In our case the bilateral dacryocystocele was diagnosed at 34 weeks gestation.

The sonographic appearance of dacryocystocele is described as a hypoechogenic mass located inferomedially to the orbit that may be seen in coronal or parasagittal view including the nose or medial angle of the orbit. Dermoid cyst is a hyperechoic entity located superolaterally to the eyeball, with areas of calcification. Hemangioma is located in the neck or head and is a solid tumor mass diagnosed by using Doppler ultrasound scanning. Anterior encephalocele is a defect located on the midline and is associated with hydrocephalus (1).

After birth, it is important to make a conclusive clinical diagnosis of meningoencephalocele: biopsy is contraindicated due to subsequent cerebrospinal fluid leakage and risk of meningitis (11, 28).

Shields (2004) mentioned that differentiation with non-inflamed dacryocystocele can be difficult because it characteristically appears at, or shortly after, birth as a pulsating swelling at the medial canthus. Examination with CT imaging usually highlights the bone defect that causes protrusion of the brain tissue (28).

As patients with dacryocystocele may have difficulty breathing and breastfeeding and risk of infection on lesion side (23) early diagnosis is essential.

The difficulties mentioned above may also lead to the occurrence of reactive psychopathological manifestations in the parents, especially in the mother. Due to their lack of experience, the primiparae are the most exposed to emotional manifestations. Any literature review reveals that over 40% of the women suffer an emotional imbalance after giving birth, even when their baby is in good health. The most commons manifestations are anxious disorders. Being already worried about their inexperience, their continuously stressful and unidirectional focus on the youngest member of their family may be sufficiently consuming to trigger an imbalance, which may variably affect their ability to care for their young and even their own health state. Although it is easily detectable and treatable, if adequate therapeutic measures are not taken, this suffering may have much more serious medical consequences than it seemed initially.

The treatment of dacryocystocele is most often or initially conservative, including lacrimal sac massage for 7-14 days to facilitate drainage of the contents into the nasal cavity, administration of topical antibiotics, warm compresses and the result is a 76% cure rate (23). Mansour *et al.*,and Harris showed dacryocystocele cases that resolved spontaneously before surgical intervention with and without a reflux of material on compression of the dacryocystocele (8,29). In our case the bilateral dacryocystocele drained spontaneously three days after birth.

There are controversial opinions on the time of surgery for congenital dacryocystocele (19). When conservative treatment fails, surgical intervention consisting of lacrimal duct probing is required. Probing reduces the risk of dacryocystitis, improving success rate (10). In the absence of treatment there is an increased risk of infection and permanent closure of the nasolacrimal duct, requiring dacryocystorhinostomy (27, 30).

CONCLUSIONS

The prenatal diagnosis of dacryocystocele is made by means of ultrasound

starting with the third trimester of pregnancy. It is essential to inform the mother about the management and prognosis of a dacryocystocele in the newborn.

This inexpensive method of investigation has an important role in reconfirming the fact that dacryocystocele is not a facial malformation, which could be a major cause of concern and distress for the mother before birth.

NEWS

IDIOPATHIC DILATED CARDIOMYOPATHY: COMPUTERIZED ANATOMIC STUDY OF RELASHIONSHIP BETWEEN SEPTAL AND FREE LEFT VENTRICLE WALL

Dilated cardiomyopathy (DCM) is the most common among the primary diseases of the myocardium and is featured, in special, by dilation of one or both ventricles and systolic dysfunction. This is a very interesting model inside a current context of major interest in studies that correlate shape and function of the cardiac pump. The geometrical alterations due to dilation observed in DCM can cause severe functional impairment. Several authors have studied the effects of these alterations in the left ventricle and developed theories that could explain the reasons for this functional impact. Through exams such as magnetic resonance, for example, verified the influence of geometrical alteration, tending to sphericity, affecting the ventricular torsion during systole or even the ventricular relaxation globally decreasing the cardiac pump performance. However, few studies have evaluated the ventricular chambers splitting them into segments, or observing the changes in size in different places inside the chambers, thus seeking for understanding the real complexity of the geometrical changes in the ill heart. These can give support to the deepening of studies about the influence of the geometrical deformation on cardiac performance as well as the development of more accurate techniques to provide a reverse remodeling. The study aimed to evaluate if, in different regions, increased transverse perimeter of left ventricular chamber in idiopathic dilated cardiomyopathy occurs proportionally between the septal and non-septal segment (free wall), in order to confirm the hypothesis that dilation occurs proportionally between these segments (Juliani PS, da Costa EF, Correia AT, et al. Idiopathic dilated cardiomyopathy: computerized anatomic study of relashionship between septal and free left ventricle wall. Rev Bras Cir Cardiovasc 2014;29 (3): 338-43).

MANAGEMENT OF TRAUMATIC LIVER LESIONS (Abstract): **Aim:** To determine the correct therapeutic approach to the different grades of liver trauma. **Material and methods:** The study is based on a retrospective analysis of treatment outcomes in 56 patients with abdominal trauma admitted over a 9-year period to in the IIIrd Surgical Clinic of the Iasi "Sf. Spiridon" Hospital. It is focused on operative or non-operative management of liver trauma, surgical technique used, morbidity and postoperative mortality. Data were collected from electronic medical records and observation sheets and processed and interpreted using Microsoft Excel statistical functions. **Results:** In the interval May 26, 2005 – April 19, 2013 56 cases of abdominal trauma were recorded, 31 (55.35%) residing in urban areas, and 25 (44.64%) in rural areas. The mean age was 39 years, range 18-83 years old. The male/female ratio was 2.5/1 and the group consisted of 40 (71.42%) male patients and 16 (28.57%) female patients. The causes of abdominal trauma were: car accident in 29 (51%) cases, fall from different heights in 6 (10%) patients, workplace-related accidents in 8 patients (14%) and direct hit injury in 12 patients (12%). In our cohort, 51 (91%) patients with abdominal trauma have been emergency admitted, 3 patients (5%) were transferred from different medical units, and 2 patients (4%) were referred by a specialist doctor. Two or more simultaneous lesions were diagnosed in 53 (96%) cases. Of the 45 patients with traumatic liver injuries diagnosed on admission, 32 (71%) required surgical intervention. In the remaining 13 (29%) patients, the therapeutic management was conservative. **Conclusions:** Hepatic traumas are often severe, and frequently associated with multiple injuries. The non-operative management is indicated in liver lesions grade I, II and III according to the American Association for the Surgery of Trauma (AAST), if abdominal cavity organs are not injured. Higher grade liver lesions (over IV) in which the hemorrhagic risk persists or reappears require surgical intervention as soon as possible, and according to the type of lesion, the right procedure should be chosen. **Keywords**: TRAUMATISM, SURGICAL, LIVER, TREATMENT.

Nowadays abdominal trauma is one of the most important parts of emergency surgery. The abdominal region is widely exposed to traumatic agents acting under a lot of circumstances: car accidents, sports, workplace accidents, violence. The management of the patient with hepatic trauma has significantly evolved over the last years partly due to the changing attitude of the medical specialists from the "interventional" one at the beginning of 60's towards the conservative (non-surgical) one in the last

20 years. Imaging analysis of liver lesions favors the decision-making regarding the therapeutic approach to be adopted, to operate or not, based on all parameters.

Liver injury is one of the most common traumatic emergency, on one hand due to the large size of the liver and fragility of the parenchyma, on the other hand due to its location in relation to the chest wall and spine, all these factors exposing it to the action of different agents which act at the level of the thoracic wall and abdomen (1-3). The management of patients with abdominal trauma and consequently of those with hepatic trauma underwent major changes in approach and concepts over the last years. These patients, victims of a true "traumatic epidemic" are usually active persons, aged 15 to 50 years. The probability of trauma-related death in this age segment is three times higher than from other causes (4).

The modern liver surgery developed in parallel with the understanding of liver anatomy and physiology, initiated by Couinaud in 1957 and later by Bismuth in 1982.

This study deals with the diagnosis, treatment, and outcome of patients with trauma to the liver (5-8).

MATERIAL AND METHODS

The inclusion criterion was traumatic liver lesion confirmed by clinical examination and laboratory investigations. The study was based on a retrospective analysis of treatment outcomes in 56 patients with abdominal trauma admitted over a 9-year interval to the IIIrd Surgical Clinic of the Iasi "Sf. Spiridon" Hospital, being focused on the operative or non-operative management of liver trauma, surgical technique used, morbidity and postoperative mortality. Ninety-one percent of patients have been admitted, investigated and treated in the Surgical Clinic, the remaining being transferred from medical units where they received primary care immediately after the accident (8%).

The term "trauma" is defined as an acute severe state following an impact of a different nature: mechanical, thermal, chemical or electric, being characterized by the presence of a physical injury which affects isolated or concomitant organs from one, two or more anatomical regions of the body (9-11). "Polytrauma patients" were the patient who sustained two or more injuries to organ systems, one of which or the combination of some lesions being life-threatening, with a severity score >16 on ISS scale, according to the definition accepted by the stuff of Floreasca Emergency University Department, Romania (12,13).

RESULTS

Diagnosis. The diagnosis of liver injury was made by history, complete physical examination, laboratory tests and imaging investigations. Abdominal ultrasound scan was performed in all patients. In case of diagnostic uncertainty or for a greater diagnostic accuracy a CT scan or abdominal MRI and/or angiography were performed. Liver function was assessed by determining the hepatic enzymes, bilirubin, cholesterol, serum iron, coagulation tests, serum proteins and albuminemia. In case of biliary obstruction, to determine its localization, extent, and cause the following were also performed: percutaneous cholangiography, ERCP (endoscopic retrograde cholangiopancreatography) and/or MRCP (magnetic resonance cholangiopancreatography).

Distribution. Analyzing the gathered data, in the interval May 26, 2005 – April 19, 2013 56 cases of abdominal trauma were recorded. Of these, 31 (55.35%) resided in

urban areas and 25 (44.64%) in rural areas.

In the study group, the mean age at injury was 39 years, range 18 - 83 years.

The male/female ratio was 2.5/1, the study group consisting of 40 (71.42%) male patients and 16 (28.57%) female patients (fig. 1). Most trauma patients were males, accounted for by the nature of activities performed by them (workplace accidents, agricultural or domestic activities), or incidents they were involved in (car accidents, conflicts and violence, sports).

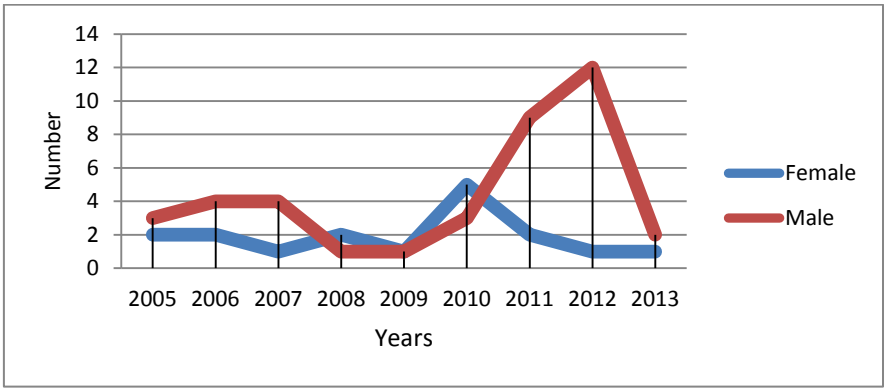

Fig. 1. The distribution of abdominal trauma patients based on sex

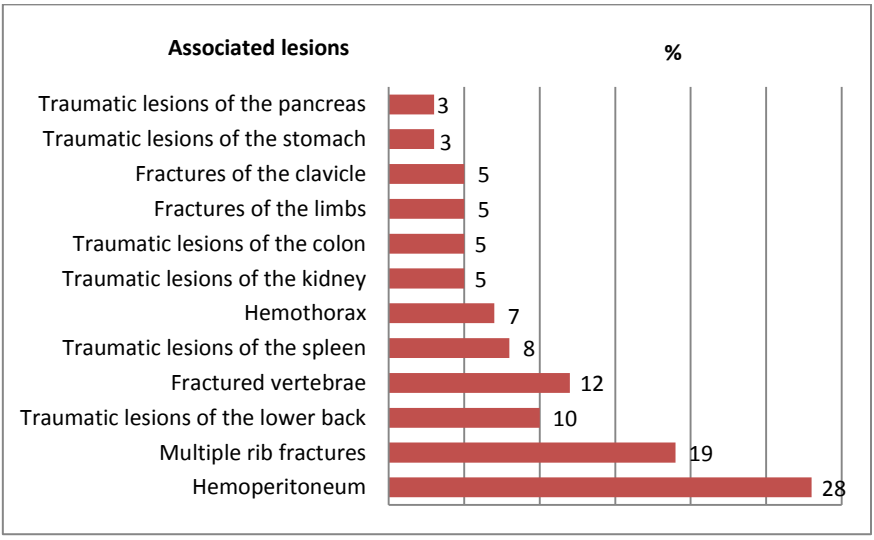

Fig. 2. Main associated lesions

Etiology. Abdominal trauma, especially that caused by car accidents which were present in 29 (51%) of our cases was the most common cause of liver injury being found in 26 (89%) of the 29 cases. Fall from different heights caused trauma in 6 cases (10%), workplace-related accidents led to abdominal trauma in 8 (14%) cases, and direct hit injury in 12 (12%) cases.

Admission type and associated lesions.

In our study group, 51 patients (91%) with abdominal trauma were emergency admissions, 3 (5%) patients were transferred from different medical units, and 2 (4%) were referred by a specialist. Of the 45 patients with liver trauma (from the total of 56 abdominal trauma patients), the great majority were polytraumatized (40 cases – 89%). Isolated liver lesions were found in 5 (11%) cases, a significantly lower value compared to frequency of liver lesions in associated trauma.

The frequency of associated lesions appears to be significant, very often two or more simultaneous lesions being diagnosed. In 53 (96%) of the cases there were concomitant lesions, their nature being detailed below (fig. 2). Hemoperitoneum was most frequently associated with abdominal trauma (16 cases/28%). Multiple rib fractures were identified in 11 (19%) patients, fractures of the vertebrae in 7 (12%) patients and of the clavicle in 3 (5%) patients. The most frequently concomitantly injured retroperitoneal organ was the spleen, 5 (8%) cases.

Traumatic lesions to the liver and gallbladder were diagnosed in 15 (34%) cases, contusion and hematoma in 18 (40%) cases, minor laceration in 7 (16%) patients, moderate laceration in 1(2%) patient, major laceration in 3 (6%) patients, and liver abscess in 1 (2%) patient (fig. 3).

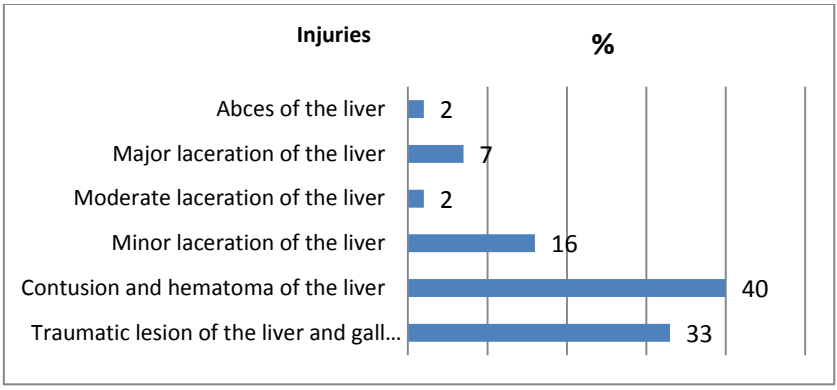

Fig. 3. Liver injuries diagnosed on admission

Type of treatment received. Of the 45 patients with traumatic liver injuries diagnosed on admission, in 32 (71%) cases a surgical intervention was required. In the remaining 13 (29%) patients, the therapeutic approach was conservative. Of the 15 patients with injuries to the liver and gallbladder, 5 (33%) patients were treated conservatively, and a surgical intervention was required in 10 (67%). As to the patients diagnosed with contusion and hematoma of the liver, in 5 (28%) cases the conservative treatment was preferred, and in the remaining 13 (72%) cases surgical intervention was required. The minor liver laceration was treated conservatively in 2 (29%) cases and surgically in 5 (71%) cases. The only case of moderate liver laceration received conservative treatment, while for major liver laceration surgery was required in all 3 patients. The patient diagnosed with a liver abscess was also surgically treated.

Patient discharge status. It should be mentioned that in 23 (51%) patients the

discharge diagnosis was cured, in 10 (22%) improved health status, in 4 (9%) patients stationary health status, and 8 (18%) patients died (fig. 4). Analyzing the number of deceased patients, we concluded that 8 of 9 patients died due to the severity of liver trauma and associated lesions.

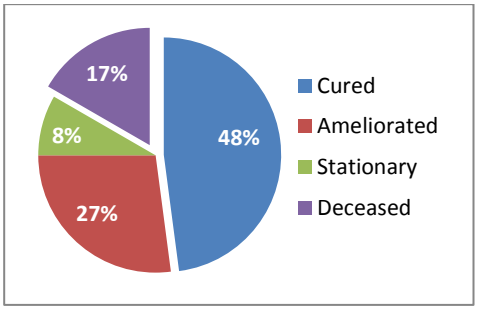

Fig. 4. Medical condition at discharge

DISCUSSION

In the last years, the frequency of liver trauma has increased considerably, and the incidence is much higher among young males aged 21-30 years and 31-40 years, thus demonstrating the social importance of the problem.

Abdominal trauma, especially that caused by car accidents identified in 29 (51%) of the patients is the most frequent cause of liver injury: 26 (89%) of 29 patients with abdominal trauma were diagnosed with liver injuries.

The failure of non-operative treatment (conservative) is influenced only by the severity of the parenchymatous organ injury associated with hemodynamic instability on admission (3).

As to mortality, none of the 8 deaths were caused by the liver trauma itself, but by the association with other severe lesions.

US and CT screening are compulsory for the correct diagnosis, stadialization of lesions, adequate treatment and prevention of possible complications (8).

CONCLUSIONS

Liver traumas are often severe, and frequently associated with multiple injuries (in 96% of the cases concomitant lesions being identified). In the vast majority of cases, the patients were admitted in emergency (91%).

The non-operative approach is indicated in liver lesions grade I, II and III according to the American Association for the Surgery of Trauma (AAST), if abdominal cavity organs are not injured. In 29% of the patients the therapeutic approach was conservative.

High-grade liver lesions (over grade IV), in which the hemorrhagic risk persists or may reappear, surgical intervention is necessary as soon as possible, and the procedure adequate to the type of lesion should be chosen. Surgery was required in 71% of cases.

NEWS

PRIMARY CLEAR CELL SARCOMA OF THE TONGUE

Clear cell sarcoma shares features with melanoma, but frequently shows EWSR1 rearrangements. It is an aggressive tumor typically occurring in the soft tissues of the extremities, with a gastrointestinal variant with less consistent melanocytic differentiation. It is extremely rare in the head and neck region, with no reported cases in the oral cavity. The authors report a case of an 82-year-old woman with a clear cell sarcoma arising in the tongue, with cervical lymph node metastases. Histologically, the tumor showed some features of gastrointestinal clear cell sarcoma. No osteoclast-type giant cells were present. The tumor cells were positive for S100 protein and negative for other melanocytic markers. Fluorescence in situ hybridization showed rearrangements of EWSR1 and ATF1. This case expands the spectrum of clear cell sarcoma with a gastrointestinal-like variant in a novel site, emphasizing the need to consider it as a differential diagnosis to melanoma in mucosal sites. This report raises the question of whether CCS of head and neck mucosal sites is a rare distinct subtype within the GI CCS spectrum, or whether this case is merely a ‘‘typical’’CCS arising in an unusual site. The morphologic and immunophenotypic features of this case support the former interpretation, but additional cases will be necessary to confirm this interpretation. Given the morphologic and immunohistochemical overlap with malignant melanoma, it is also possible that such cases were previously diagnosed as melanoma. In agreement with that, a recently published study performed on cases from the GI tract that were diagnosed as melanoma showed that a small fraction in fact were CCS. While future studies may answer this question, the practicing pathologist should be aware of CCS when encountering an S100 protein–positive epithelioid and spindle cell neoplasm arising in an unusual site without diagnostic features of melanoma, such as an in situ component, and should have a low threshold for performing additional molecular studies to further investigate this possibility (Stefan Kraft, Cristina R. Antonescu, Andrew E. Rosenberg, Daniel G. Deschler, G. Petur Nielsen, Primary Clear Cell Sarcoma of the Tongue. Arch Pathol Lab Med. 013;137:1680–1683).

PREGNANCY AND RECURRENCE RATES IN INFERTILE PATIENTS OPERATED FOR OVARIAN ENDOMETRIOSIS

Monica Holicov Luţuc[1], D. Nemescu[1], Alina Onofriescu[2], Mihaela Târnovanu[1], Mihaela Moscalu[3*], M. Onofriescu[1]

PREGNANCY AND RECURRENCE RATES IN INFERTILE PATIENTS OPERATED FOR OVARIAN ENDOMETRIOSIS (Abstract): **Aim:** The study deals with the preoperative ultrasound diagnosis of ovarian endometriosis, postoperative ultrasound reassessment, laparoscopic surgical resolution of ovarian endometriosis, estimation of recurrence risk 12 months after surgery by ultrasound, reappearance of clinical symptoms (such as pain) or second-look laparoscopy, and pregnancy rate 2 years after surgery. **Material and methods:** 140 patients with endometriosis and infertility admitted to the Iasi "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology between the years 2009-2011 were included in the study. The patients were divided into 2 groups: group 1 - 59 cases that refused in vitro fertilization procedures, did not afford in vitro fertilization (IVF) or had minimal endometriosis and young ages and thus a possibility of delaying treatment, and group 2 - 62 cases which underwent IVF procedures immediately after surgery. **Results:** No significant differences in the chance of becoming pregnant were found between the two groups (χ^2=2.06, p=0.0891, 95% CI); in group 1, 11.86% pregnancies were obtained while in group 2 the pregnancy rate was 11.29%. Based on the nonparametric method of analysis of contingency tables we could estimate the odds of becoming pregnant in the study groups, obtaining an odds ratio (OR=1.16, CI: 1.04-2.23, 95% CI). This result indicated that in group 1 the odds of becoming pregnant was not significantly higher, and the estimation was made for a confidence interval of 95%. The study had in view the assessment of pregnancies obtained in the study groups and the time interval (number of weeks) from the time of intervention until the occurrence of pregnancy. The Kaplan-Meier analysis enabled the assessment of the mean value and the median value of the number of weeks until becoming pregnant, and these values did not show significant differences (χ^2=1.55, p=0.212, 95% CI). **Conclusions:** For endometriosis associated with infertility, hormonal suppression does not improve fertility, and therefore surgery followed by controlled ovarian hyperstimulation and intrauterine insemination (IUI), provided the anatomy of the pelvis is preserved in early cases or *in vitro* fertilization in severe cases is preferred. **Keywords:** ENDOMETRIOSIS, INFERTILITY, PELVIC PAIN, LAPAROSCOPY.

Endometriosis is a benign disease characterized by the growth of the endometrium outside the uterus under the influence of estrogen. This cyclical growth followed by bleeding in the surrounding tissue determines symptoms such as pain and infertili-

ty. The only form of endometriosis diagnosed preoperatively by noninvasive means is the ovarian endometrium, which is the formation of a cyst full of blood inside the ovary. The most common forms are the intraperitoneal ones, but distance localizations are not excluded. Optimal treatment is surgical laparoscopy to remove the endometrial tissue by ovarian stripping or hormonal suppression. In most cases it is followed by relapses.

Endometriosis is a hormone-dependent progressive disease, which can be responsible for symptoms like: dysmenorrhea, dyspareunia, chronic pelvic pain and infertility. After 150 years of research, when multiple hypotheses were issued, the etiology of endometriosis remains unknown. No theory can fully explain the clinical manifestations; therefore, endometriosis can rather be viewed as a syndrome. The diagnosis is often established macroscopically by laparoscopy; histological confirmation is essential because in several cases the endometrial origin of these lesions is invalidated. In the literature, the prevalence of endometriosis varies significantly according to the method of diagnosis: 2-78% in infertility, 0.7-43% in celioscopy for tubal ligation and 4.5-82% in patients who underwent surgery for pain (1). In teenagers with severe dysmenorrhea or pelvic pain, endometriosis is diagnosed by celioscopy in 50% of the cases (2). There are no relevant epidemiological data regarding the incidence of endometriosis in the general population.

The study dealt with the preoperative ultrasound diagnosis of ovarian endometriosis, ultrasound reassessment after surgical treatment, laparoscopic surgical resolution of ovarian endometriosis, estimation of recurrence risk 12 months postoperatively by ultrasound, reoccurrence of clinical symptoms such as pain or by second-look laparoscopy, and the pregnancy rate 2 years after surgery. The aim was to highlight the role of conservative surgery in the treatment of endometriosis-related infertility and the increase of recurrence rate following ovarian hyperstimulation.

MATERIAL AND METHODS

One hundred and forty cases of endometriosis and infertility admitted to the Iaşi "Cuza−Vodă" Hospital of Obstetrics and Gynecoogy between the years 2009-2011 were included in this study. The age distribution showed that 25% of the patients were older than 33 years (quartile interval Q75-33 years) with a mean age of 29.7 years ±4.9SD, while 50% of these were younger than 26 years (median – 26 years). We did not use the R-AFS classification because of its known subjectivity, and the cases were classified according to the size of the endometriomas: 100 cases of unilateral or bilateral endometriomas less than 5 cm in size and 40 cases with endometrial cysts over 5 cm.

The patients included in the study had a ultrasound diagnosis of unilateral or bilateral ovarian endometriosis histologically confirmed after laparoscopy. The conventional ultrasound diagnostic criteria were: presence of ovarian cysts with characteristic appearance, with a non-homogenous "ground glass" appearance and/or hyperechogenic wall foci with absence of vascularization on power Doppler. The cyst size ranged from 2 cm to 11 cm. The ultrasound signs of deep endometriosis were not looked for. Doctors explained to all patients the pathophysiology of the disease and its repercussions on fertility and quality of life. Patients who refused any intervention or did not come back for consultation were excluded from the study.

Inclusion criteria: age above 18 years, endometrioma over 3 cm and infertility, absence of pregnancy, absence of associated pathologies that do not indicate laparoscopic intervention, the patient's expressed wish for immediate diagnosis, history of previous IVF failure, association of other causes of infertility. *Exclusion criteria:* pregnancy, patients who opted for hysterectomy with bilateral adnexectomy, patients with endometriomas not associated with infertility or who did not want children, endometriomas less than 2 cm in size (oral birth control pills were recommended), relapse after a new intervention.

Informed consent for the participation in this clinical study was obtained from all patients after the diagnosis of ovarian endometriosis was made. The consent for laparoscopy was obtained upon admission for the surgical intervention.

All participants in the study were included in a database where the following were recorded: age, weight, menarche, last menstruation, duration of cycles and interval between cycles, previous hormonal treatments, duration of symptoms, ultrasound cyst size, unilaterality or bilaterality, presence or absence of hydrosalpinx, clinical stability or mobility of cysts, previous admissions, preoperative CA125 levels and possibly preoperative AMH levels, and type of surgery. The pre-anesthesia consultation included the laboratory exam, the cardiologic consultation and the chest X-ray.

Of the 140 patients with ultrasonographically suspected endometriosis, only 121 cases (86.43%) were operated of which 7 opted (5%) for hysterectomy with bilateral adnexectomy and 12 patients (8.57%) had other diagnoses (dermoid cyst: 4, hemorrhagic cyst: 8). These 121 patients who remained in the study were then divided into two groups depending on a series of factors which influenced decision making in the performance of laparoscopic surgery: history of infertility and other possible causes (male sterility); size of the endometrioma and the anatomic distortion of the pelvis; unilateral or bilateral hydrosalpinx; history of tubal or ovarian surgery; age, presence of the pelvic pain syndrome, other coexisting factors influencing the couple fertility, the patient's wish, if the patient can afford the costs knowing that in Romania the fertilization procedures are not reimbursed by the Health Insurance Fund.

Group 1 - 59 patients who did not want IVF, did not afford IVF or had minimal endometriosis and young ages with possibility of delaying the treatment. Characteristics of the group: infertility without other associated causes: adherences, hydrosalpinx, preservation of pelvic anatomy, bilaterally positive methylene blue test, no history of inflammatory disease.

Group 2 - 62 patients who underwent IVF procedures immediately after surgery. Characteristics of the group: infertility, changes of pelvic anatomy by adherences or unilateral or bilateral hydrosalpinx, other associated causes of infertility. The group consisted of: 59 patients (95.16%) aged between 25 and 39 years with primary infertility and 2 cases (3.22%) with primary infertility and male infertility. The mean duration of infertility was 4 years. Tubal infertility was associated with unilateral or bilateral hydrosalpinx in 10 cases (16.13%), previous surgery in 3 cases (4.84%) and history of failed IVF in 6 cases (9.68%).

The 2 groups were compared with respect to the recurrence of endometriosis one year postoperatively (based on MRI, ultrasound, repeat laparoscopy, or reoccurrence of pain) and pregnancy rate following various treatment methods.

RESULTS

We conducted a comparative study of two homogenously distributed groups of patients with endometriosis and infertility. The 121 patients (86.43%) who had infertility and unilateral or bilateral ovarian endometriosis were advised to try to conceive as soon as possible after surgery, either naturally or by IVF. In the 62 patients (51.23%) in group 2, bilateral hydrosalpinx followed by tubal coagulation, older age, large cysts with multiple adherences, low preoperative AMH level or patient's desire for fertility were the main indications for recommending reproductive medicine immediately after interventional laparoscopy. In milder cases, with unilateral endometriomas of small sizes, preserved tubal permeability at the methyl blue test, younger age under 30 years, the patient's financial situation or lack of desire for immediate fertility, were indications for getting pregnant naturally.

During laparoscopy, the cysts were removed by ovarian stripping, the endometrial implants were coagulated and the adhesions were totally or partially lysed; in case of hydrosalpinx, the tubes were cauterized or even removed by salpingectomy for successful IVF. In 3 instances laparoscopy was re-converted to laparotomy: in the first case, for large bilateral cysts, with multiple adhesions, in the second case, for suspicion of ovarian neoplasm, confirmed by extemporaneous exam, and in the third case, for difficult hemostasis. The excision of endometriomas was made with observing the ovarian vascularization, without excessive coagulation and with observing the remaining ovarian cortex to preserve the follicular reserve. Tubal permeability was tested in all cases in order to make a decision regarding the possibility of becoming pregnant by natural way after the removal of endometriosis. All cases with proximal obstruction were counselled for immediate reproductive medicine. The study had in view particularly the chances of becoming pregnant and the occurrence of recurrences (fig. 1).

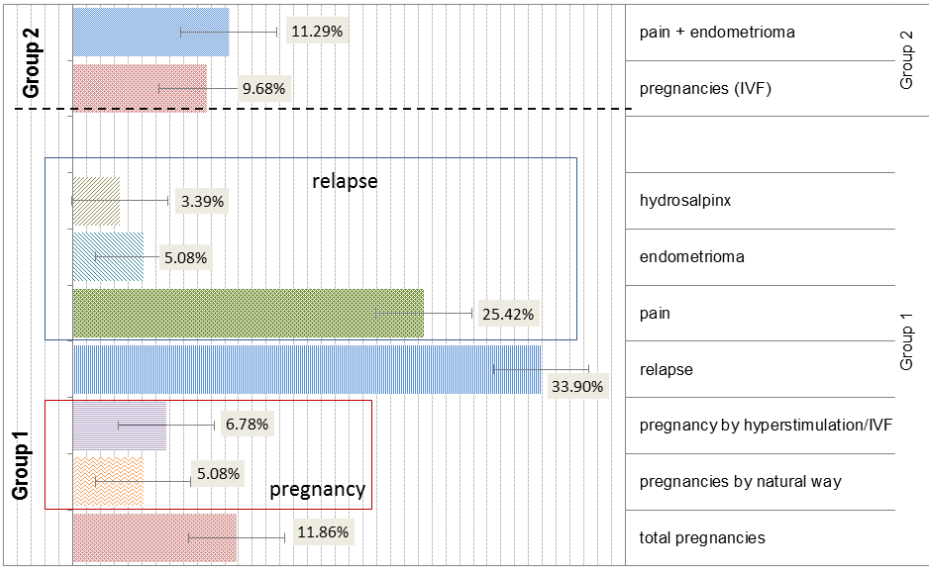

Fig. 1. Pregnancies and recurrence rate

In group 1, 3 (5.08%) natural pregnancies were obtained. The expectancy for pregnancy was 1 year. At the end of the year, the patients were called for ultrasound and clinical re-assessment and reconsidering the therapeutic decision. Pain reoccurred after 1 year in 15 cases (25.42%), and endometrioma in 3 cases (5.08%), but in all 3 cases its size was under 2 cm. The hydrosalpinx occurred postoperatively in 2 cases (3.39%) probably as a result of adhesion formation and change in pelvic anatomy. The remaining 56 patients were counselled for reproductive medicine, 2 pregnancies being obtained following hyperstimulation with *clomiphene*, without intrauterine insemination (IUI), 1 pregnancy following hyperstimulation with gonal and IUI and only one pregnancy following 17 IVF procedures performed in 10 patients. The total number of obtained pregnancies was 7 (of 59 patients - 11.86%). Clinically or ultrasonically detected recurrence occurred in 3 cases (5.08%).

In group 2, 240 IUIs were performed of which only 20 by natural cycle without ovarian hyperstimulation and only 2 pregnancies were obtained, and 4 twin pregnancies were obtained from 80 IVFs; therefore, the pregnancy rate was 6 of 61. Recurrences occurred in 7 cases by reoccurrence of pelvic pain and ovarian endometriosis. A laparoscopic reintervention for adhesions lysis was performed in all 7 cases. In the 2 cases with recurrence of endometriosis stripping was difficult because of adhesions and postoperative fibrosis. In the 7 re-operated cases IVF was performed, but only one pregnancy was obtained. Patients older than 35 years with recurrence did not get pregnant (the patient who got pregnant was 28 years old).

From the point of view of becoming pregnant, no significant differences between the two groups were found (χ^2=2.06, p=0.0891, 95% CI); in group 1, 11.86% pregnancies were obtained while in group 2 the pregnancy rate was 11.29%. Based on the nonparametric method of analysis of contingency tables we could estimate the odds of becoming pregnant in the study groups, obtaining an odds ratio (OR=1.16, CI: 1.04-2.23, 95% CI).This result indicates that the odds of becoming pregnant in group 1 was not significantly higher, and the estimation was made for a confidence interval of 95%.

TABLE I

Estimated parameters in the Kaplan-Meier analysis of pregnancy rate in the two study groups

Means and Medians for pregnancies

	Mean[a]				Median			
	Estimate (weeks)	Std. Error	95% Confidence Interval		Estimate (Weeks)	Std. Error	95% Confidence Interval	
			Lower Bound	Upper Bound			Lower Bound	Upper Bound
Group 1	27.663	1.345	25.028	30.299	24.000	.571	22.880	25.120
Group 2	30.951	1.652	27.714	34.188	24.000	1.171	21.706	26.294
Overall	29.572	1.113	27.391	31.754	24.000	.446	23.127	24.873

a. Estimation is limited to the largest pregnancies time if it is censored.

The study had in view the assessment of pregnancies obtained in the study groups and therewith, the time interval (number of weeks) from the time of intervention until the occurrence of the pregnancy. The Kaplan-Meier analysis (fig. 2) enabled the assessment of the mean value and the median value of the number of weeks until

becoming pregnant, and these values did not show significant differences (χ^2=1.55, p=0.212, 95% CI).

The mean time interval (weeks) between intervention and becoming pregnant was 29.5 weeks, and the median valued indicated that 50% of cases got pregnant in the first 24 weeks after the intervention (table II). The Kaplan-Meier curves clearly showed an absence of significant differences between the pregnancy rates in the two study groups (fig. 2).

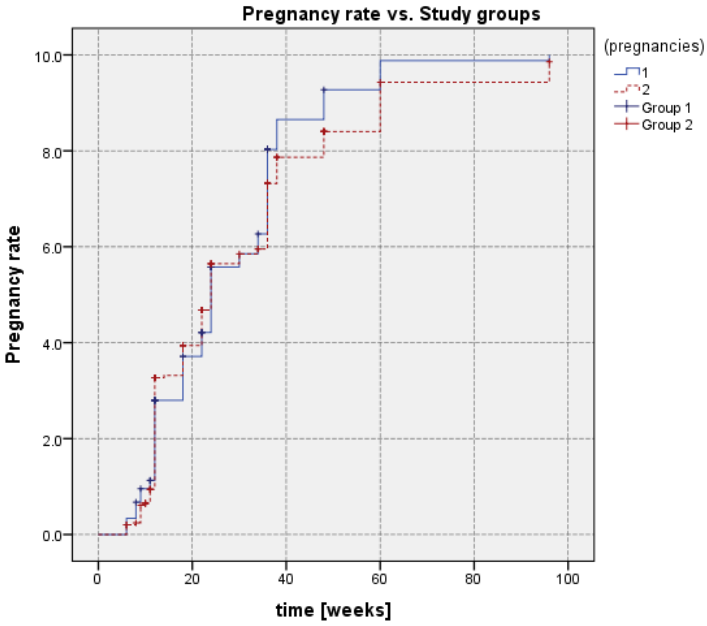

Fig.2. Kaplan-Meier curves of pregnancy rate in the two study groups

DISCUSSION

In two cohort prospective studies on infertile women with moderate and severe endometriosis (AFS classification) who underwent laparoscopic surgery, the pregnancy rate was 57–69% (moderate endometriosis) and 52–68% (severe endometriosis) (3, 4). In our study, the pregnancy rate was much lower (maximum 11.86%), but we did not use the R-AFS classification.

Data in the literature suggest that cystectomy increases the pregnancy rate compared to drainage and electrocoagulation of the cyst (5). In our study, following cystectomy 7 patients got pregnant although they had a history of infertility of 2 to 16 years

(mean 4 years) and of drained endometriomas without cystectomy. One patient who was infertile for 16 years and had bilateral endometrial cyst got spontaneously pregnant 3 months after the surgical intervention. Both surgical techniques, ablation and drainage, can affect the ovarian reserve, but it appears that pregnancy rate is higher after cystectomy (6).

There are no comparative studies on pregnancy rate between the expectant management after laparoscopic surgery and the active management by human assisted reproduction techniques. In our case, there were no significant differences in pregnancy rate between the two groups (6.78% group 1 *vs.* 9.68% group 2). A bias would be related to the fact that no intracytoplasmic sperm injection (ICSI) was performed in any of the patients and another one by the fact that patients with an AMH lower than 1 ng/ml were not accepted for IVF. A meta-analysis on 22 studies (7) demonstrated that women with endometriosis have a pregnancy rate below 35%. Our study confirmed this finding.

The therapeutic approach depended on the desire and individual characteristics of the patient: age, number of previous interventions, failure or success of previous therapies, endometrioma size, tubal damage, and exclusion of occult malignancies

Human assisted reproduction as a first choice before laparoscopy has a low success rate and high costs, being the first choice only in women older than 35 years (8, 9). Postoperator terapeutic management can be used to delay surgery until fertility is desired (10).In Romania the reported endometriosis rate has increased alarmingly, either because of the advances in diagnosis (ultrasound diagnostic laparoscopy) or because more women who have chronic pelvic pain or infertility seek medical advice (11). Therefore, gynecologists should be prepared to counsel such patients. It is the doctor's duty to make a diagnosis as early as possible and to inform the patient about the possibility of disease recurrence and the associated infertility. After making the diagnosis, which most of the time is late, it is necessary to establish a treatment protocol, which most of the time does not consider the Hippocratic principle *primum non nocere*, because the disease is so invalidating through the chronic pelvic pain that the only therapeutic option is total hysterectomy. Affected women are usually nulliparous, and the recommendation of a radical surgical procedure for removing all endometrial fragments, which practically would lead to the relief of pain caused by the endometrial implants, would put the patient in the impossibility of conceiving a child in the future (12,13,14).

CONCLUSIONS

In our study, in spite of a strong relation of causality between endometriosis and infertility, it is clear that treatment of endometriosis may improve fertility in some cases. Expectant management can by a reasonable approach in younger patients with less severe disease and a shorter period of infertility.

Laparoscopic surgery seems a better approach compared to medical therapy in endometriosis increasing the odds of spontaneous pregnancies by reconstructing the pelvic anatomy after adhesiolysis.

The pregnancy rate after immediate post-cystectomy procedures is equal to that of patients on postoperative expectant management. Expectant management should be indicated only in younger patients with perfect pelvic anatomy and

without associated causes for obtaining a spontaneous pregnancy. Recurrence risk is equally high after expectant management or human assisted reproduction.

In women with minimal to mild endometriosis, IUI with controlled ovarian stimulation may be effective in increasing live birth rate, compared with expectant management. Furthermore, IUI with controlled ovarian stimulation may be more effective in increasing pregnancy rate than IUI alone, and may be as effective in women with minimal or mild endometriosis within 6 months of surgical treatment as in women with unexplained infertility.

Based on the conducted study we can recommend controlled ovarian hyperstimulation treatments followed by intrauterine insemination which are better, cheaper and easier options than IVF, only if the surgical anatomy of the pelvis is corrected by the lysis of adhesions, removal of cysts and positive bilateral dye test. Postoperative active intervention through procedures of assisted reproductive medicine increases the pregnancy rate (11.86%) regardless of the size of the endometrioma compared to the passive management.

LAPAROSCOPIC TREATMENT OF A LARGE SYMPTOMATIC LEIOMYOMA OF THE ROUND LIGAMENT (Abstract): Round ligament leiomyoma are very rare benign tumors. They can appear on the extraperitoneal part of the round ligament (more common) or on the intraperitoneal round ligament (very rare). We present a case of 48-year-old women diagnosed with a large (122/108/98 mm) intraperitoneal leiomyoma of the left round ligament that was managed by laparoscopy. Laparoscopy proved to be a highly useful method, overcoming the limitation of ultrasound or CT and providing a safe and minimally invasive treatment method. **Keywords**: ROUND LIGAMENT LEIOMYOMA, LAPAROSCOPY, ROUND LIGAMENT TUMOUR.

Although uterine myoma is one of the most common benign gynecologic pathology, extra-uterine myoma are quite rare. Extra-uterine myoma usually appears in the genito-urinary tract (vulva, broad ligament, ovaries, round ligament, urethra). Round ligament leiomyoma are very rare benign tumors. The exact incidence of round ligament myoma is not known, specialized literature presenting several cases, most of them case report or mini-series. Usually they appear in the extraperitoneal round ligament and rarer in the intraperitoneal round ligament. The myoma of the left intraperitoneal ligament are considered extremely rare (1, 2). This is the case of a large leiomyoma of the round ligament situated in the left intraperitoneal round ligament, initially diagnosed as pedunculated uterine myoma, and managed by laparoscopy.

CASE REPORT

A 48-year-old pregnant female, came to gynecology for abdominal pain for several months, treated intermittently with non-inflammatory steroids. Her past medical history was unremarkable. Speculum examination revealed normal cervix and vagina. On vaginal examination, the uterus was deviated to the right, normal in size, with a large non-tender mobile solid lobulated mass, palpated in the left iliac fossa. Abdominal and endovaginal ultrasound revealed a myoma-like tumor 100/90/100 mm situated to the left side of the uterus (fig.

1,2). Computed tomography (CT) scan confirmed the presence and the size of the tumor mass (122/109/98mm) localized in the left iliac fossa. The established diagnosis was a pedunculated uterine myoma. A laparoscopy was scheduled after careful explanation and informed consent from the patient. Intraoperatory it was observed a large myoma-like mass originating in the left round ligament of the uterus (fig. 3,4). The uterus, both ovary and tubes were normal and well delineated from the tumor. The mass was removed entirely and histopathology result confirmed the diagnosis of leiomyoma. The post-operative course was otherwise uneventful and patient was discharged the second day after the operation.

DISCUSSION

The round ligament is a fibrous band attached to the uterus and extends laterally and anteriorly, hooks around the inferior epigastric artery, traverses the inguinal canal, and terminates in the *labium majus*. It is responsible for the descent of the ovary from the posterior abdominal wall to the uterus. The round ligament is accompanied in the fetus, and occasionally in the adult, by a process of peritoneum, the processes vaginalis. The round ligaments consist principally of muscular tissue, prolonged from the uterus and fibrous and areolar tissue, besides blood vessels, lymphatics and nerves.

Tumors of the round ligament are rare, the exact incidence it is not known. Among these tumors, leiomyomas are the most frequent, followed by endometriotic tumors. Various very rare tumors can also be found. Transformation of muscular structure of the female genital tract to leiomyoma involves somatic mutations of normal smooth muscle and complex interactions between sex steroids and local growth factors (3). Smith et al (4) demonstrated that both estrogen and progesterone receptors are found in round ligament. The presence of these receptors could explain why the majority of cases described in the literature were diagnosed during perimenopause. There are also several cases describes during pregnancy or menopause (2, 3, 5, 6).

Approximately one half to two-third of round ligament leiomyomas appear in the extraperitoneal part of the round ligament and for unknown reason are more common on the right side (7). Exceptionally a tumor can have a both abdominal and extraperitoneal development from the inguinal insertion (8). When they appear in the inguinal canal they can be misdiagnosed as incarcerated hernia, cyst of the Nuck canal, thrombosis of varicose veins around round ligament. They also can be diagnosed as complications by incarceration in the inguinal canal (9). Tumors of the intraperitoneal cavity can be misdiagnosed as ovarian tumors or pedunculated uterine myoma, like in our case. Therefore fibroids should always be kept in mind during the differential diagnosis of any pelvic mass. The size can vary widely from 2-3 cm when they can be discovered incidentally to more than 10-20 cm, cases that are usually symptomatic.

A useful tool for diagnosis is the ultrasound examination where typically a myoma has whorled pattern appearance with variable echogenicity, depending on the presence of degeneration and calcification. In some cases cystic degeneration with extensive edema forming cystic, fluid-filled spaces can appear and the diagnosis can be more difficult to establish. Magnetic resonance imaging (MRI) is the best diagnostic modality, as it can make the difference from round ligament fibroids, ovarian masses or broad ligament mass. But even in MRI confusion can persist in presence of degenerative changes like hyalinization or cystic degeneration. Another pitfall for the diagnosis is the fact that sometimes, round ligament fibroids can mimic a pseudo-Meig's syndrome with elevated CA-125 pointing towards metastatic ovarian carcinoma (10). In these cases differentiating round ligament fibroids from ovarian masses before surgery is a diagnostic challenge. As we see, imaging techniques can sometimes misdiagnose these tumors. In these difficult cases, laparoscopy is a valuable tool not only for diagnosis but also for its possibility to excise these tumors.

When the tumor is situated in the inguinal canal, the surgical approach is inguinal and some authors recommend a formal inguinal hernia repair technique, performed preferably with mesh (9). However, other types of hernia repair without mesh could also be considered depending on surgeons' preference. When the tumor is intraperitoneal the management depends on the age of the patient, the desire to preserve fertility or other associated condition (like uterine myoma). A laparoscopic conservative approach represented by laparoscopic myomectomy is feasible in young patients who desire to preserve fertility.

We confirm with our case the highly valuable role of laparoscopy, which not only overcomes the limitation of imaging, ultrasound or CT, but also provides a safe and minimally invasive treatment method.

CONCLUSIONS

In our study we observed that a large round ligament fibroid is a rare entity and can be easily mistaken for a uterine pedunculated myoma when it develops in the intraperitoneal ligament. Leiomyoma of the round ligament must be retained as a possible etiology of inguinal mass or pelvic tumor. Laparoscopy overcomes the limitation of imaging, ultrasound or CT, but also provides a safe and minimally invasive treatment method even in a large myoma.

TREATMENT OF PROXIMAL HUMERAL FRACTURES USING THE "TELEGRAPH" ROD: RETROSPECTIVE STUDY OF 47 CASES (Abstract**): Aim:** To assess the early results observed in a series of patients treated with a first-intention Telegraph rod. **Material and methods:** In the interval 2011-2013 forty-seven patients with fractures of the upper extremity of the humerus were assessed both clinically and radiologically. Mean follow-up was 8.9 months. The median age was 61 years. The study group included 39 women and 8 men, the left shoulder being most commonly affected (33 cases). Cause of injury was accidental fall in 39 cases fall, sports injury in 6 cases, and car crash injury in 2 cases. Neer classification was used to assess the type of fracture. For qualitative analysis, we used the functional *Constant-Murley score* in comparison with the contralateral side. The analysis of fracture reduction was based on plain X-rays in anterior-posterior plane and measurement of humeral head tilt relative to diaphyseal shaft. **Results:** No case showed infection, humeral head necrosis occurred in 2 cases, loss of reduction in 3 cases which required repeat reduction, and a subacromial impingement syndrome in 2 cases. Average *Constant-Murley score* was 70.33 points for the injured and 86.4 points for the healthy shoulder. Mean value of reduction angle of the humeral head relative to diaphyseal shaft was 33.75 degrees (range 3 to 81 degrees). **Conclusions:** Telegraph rods provide a secure fit in extra-articular and simple articular fractures of the proximal humerus. When performing a closed anatomical reduction, the method provides good functional results in most patients. This option should be considered in young patients and even in the elderly, the results being comparable to those obtained by hemiarthroplasty. **Keywords:** HUMERAL FRACTURES, RETROSPECTIVE STUDY, TELEGRAPH ROD

The incidence of proximal humeral fractures is increasing accounting for 5.7% of all fractures (1). This increase occurs mainly in the elderly, osteoporotic people (1-5). Treatment options range from orthopedic treatment to intra medullary rods, open reduction with internal fixation or arthroplasty. Fractures without/with minimal displacement should usually be treated conservatively, a good functional outcome for this group of fractures being reported (6). Fortunately, 70-80% of these fractures can be treated conservatively. On the other hand, there is a consensus that displaced for four-part fractures and/or comminuted fractures, fractures-dislocations in the elderly should be treated with primary hemi arthroplasty (7).

Minimally invasive techniques with closed reduction began to be supported in order to preserve the soft tissue, vascularization of the humeral head and fracture

fragments. Therefore, many surgeons choose to use intramedullary rods suitable for fixing the fracture, while others tend to favor the use of locked plates (8-11).

AIM

The purpose of this study was to evaluate the early results observed in a number of patients treated with a first intention Telegraph rod.

MATERIAL AND METHODS

In the interval 2011-2013, 47 patients with fractures of the upper extremity of the humerus were assessed clinically and radiological. Mean follow-up was 8.9 months (range 7 -12 months). The median age was 61 years (range 29-87 years). The study group included 39 women and 8 men, the left shoulder being most commonly affected (33 cases). Cause of injury was accidental fall in 39 cases (82.97%), sports injury in 6 cases (12.76%) and car crash injury in 2 cases (4.25%). To assess the type of fracture we used Neer classification (group A - fractures with two fragments, 31/47 cases (65.95%), group B - 3 fracture fragments, 13/47 cases (27,65%), group C - 4 fracture fragments, 3/47 cases (6,38%).

The surgical technique consisted of: loco-regional anesthesia, the patient in supine position, closed/open reduction, incision of about 4 cm above the acromion, based on the greater tuberosity, transdeltoidian. Site of rod insertion was at the edge of the articular surface between it and the greater tuberosity, in the middle of the humeral head. The rod was inserted with gentle movements of rotation. It was positioned in the center of the humeral head under Rx-TV control and fixed with screws. Distally the rod was fixed with one or two screws.

The average time of surgery was 30 minutes (range 25-47 minutes). Postoperatively the affected upper limb was immobilized in a scarf for two weeks and physiotherapy was initiated after 2-4 weeks depending on fracture characteristics. Clinical and radiological follow up was performed at 1, 3, 6, 12 months (fig. 1, 2).

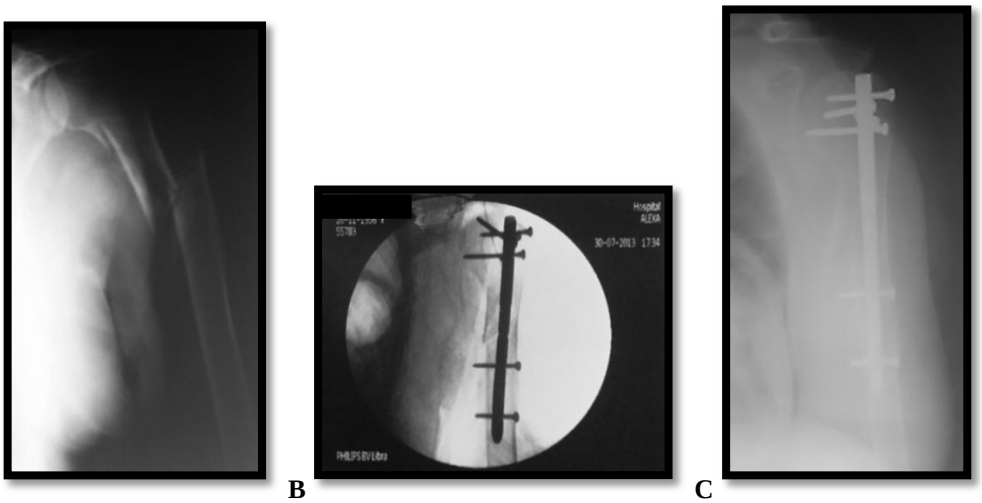

Fig. 1. Patient M.R., M, 46 years old: **A –** bifocal fracture of the proximal humeral extremity, **B -** fluoroscopic control immediately after surgery, **C –** X-ray control at 3 months.

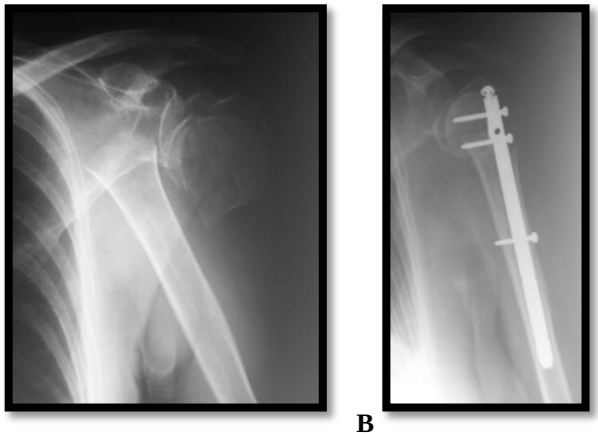

Fig. 2. Patient A.E., F, 59 years old: **A –** fracture-dislocation of the proximal humeral extremity Neer IV, **B –** X-ray control at 1 month.

All fractures healed within 1 to months. For qualitative analysis we used the functional *Constant-Murley score* in comparison with the contralateral side. For the analysis of fracture reduction we used plane X-rays in anterior-posterior view and measured the humeral head tilt relative to diaphyseal shaft. Normally this angle is 45 degrees. Reduction was considered adequate for an angle between 30 degrees and 60 degrees.

RESULTS

No case showed infection, humeral head necrosis occurred in 2 cases, loss of reduction in 3 cases requiring repeat reduction, and subacromial impingement syndrome in 2 cases that led to rod removal at 6 months (fig. 3).

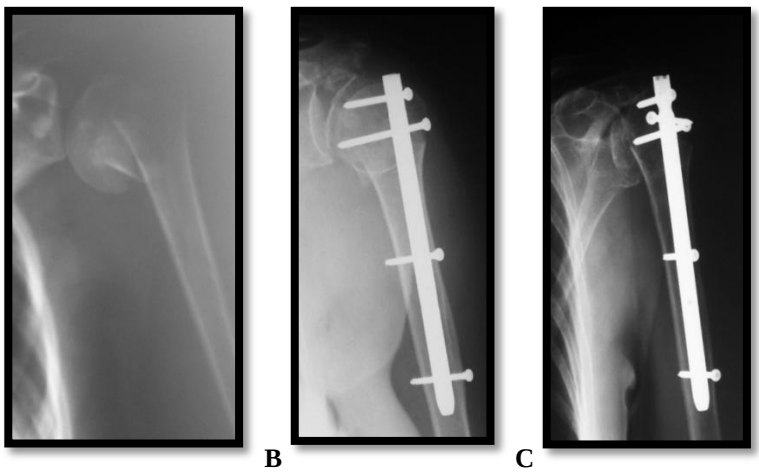

Fig. 3. Patient R.I., F, 65 years old: **A –**fracture of the proximal humeral extremity Neer III, **B -** X-ray control at 1 month, **C –** X-ray control at 3 months - loss of reduction with subacromial impingement syndrome.

Average *Constant-Murley score* was 70.33 points (range 39-98 points) for the injured and 86.4 points the healthy shoulder. Average *Constant-Murley score* for group A was 78.5 points (range 59-98 points), group B - 70.5 points (range 36-82 points), and group C - 62 points (range 49-75 points).

The mean head-shaft angle reduction 33.75 degrees (range 3 to 81 degrees). In group A reduction was considered good in 24 cases (77.41%) and poor in 7 cases (22.58%), in group B the reduction was considered good in 7 cases (53.84%) and poor in 5 cases (38.46%), and in group C reduction was considered good in 2 cases (66.66%)and poor in 1 case (33.33%).

DISCUSSION

A good surgical fixation should include anatomic reduction of the tuberosities, restoration of length, alignment and rotation of fragments. This should be done with minimal trauma to soft tissue, preserving the medial periosteal hinge and blood supply. To prevent impingement, the amount of hardware to the cortical surface should be minimal. In a biomechanical cadaver study, intramedullary fixation proved to be more stable and more resistant than traditional plate or plate locked with screws (12). This allows for stable fixation through a small incision with minimal soft tissue damage, facilitating early mobilization and functional recovery of the shoulder.

Cuny et al. (13) followed the results obtained after using 64 telegraph rods. They were favorable, including patients with complex fractures involving three or four pieces. In addition to providing a stable anatomic reconstruction, Telegraph rod has the advantage of allowing early mobilization of the shoulder joint, this method being considered a useful alternative to prosthetic reconstruction for traumatic fractures of the proximal humerus.

Blum et al. (14) treated 151 unstable fractures of the proximal humerus with two and three fragments, and observed as complications: articular surface piercing (n= 8), pain related to the implant (n=10), secondary displacement (n=2), nonunion (n=2), necrosis of the humeral head (n= 3) and superficial infection (n=1). Functional results obtained were good, *Constant-Murley score* having an average value of 75.3 compared with 89.9 in the healthy shoulder. Cuny et al. (15) retrospectively analyzed 67 patients with proximal humerus fractures treated with telegraph rod and noticed that this technique provides a reproducible and satisfactory surgical result for cervical and valgus impacted fractures, the result being less satisfactory for unstable fractures or fracture-dislocations joint (avascular necrosis - 37.5%, secondary displacement in all 6 cases tuberosity fractures with four sides, subacromial impingement in 8 cases).

Popescu et al. (16), based on the results obtained after treating 21 fractures of the proximal humerus through osteosynthesis with T2 PHN, indicate that it is a safe and reliable method in the treatment of two- and three-parts proximal humeral fractures. Proximal fixation mechanism decreases the rate of screw slippage, a common complication described in the literature. Good functional results were obtained in patients younger than 70 years, but these were not statistically significant.

Thomazeau et al. (17), treating 51 patients with unstable 3-part or 4-part proximal humerus fractures, concluded that telegraph rod fixation can be recommended for 3-part fractures, because osteonecrosis

is uncommon and well tolerated in this subgroup. However, this method was not more beneficial than other techniques of internal fixation to prevent osteonecrosis or malunion in patients with 4-part fractures.

CONCLUSIONS

In our study, telegraph rods provides a secure fit in extra-articular and simple articular fractures of the proximal humerus. When performing a closed anatomical reduction, the method provides good functional results in most patients. This option should be considered in young patients and even in the elderly, the results being comparable to those obtained by hemiarthroplasty.

HISTOLOGIC AND IMMUNOHISTOCHEMICAL ANALYSES OF ENDOMETRIAL CARCINOMAS

Endometrial cancer is one of the most common malignancies of the gynecologic tract. Endometrial cancers are classified into 2 broad histologic types, defined as type I and type II. Type I consists of endometrioid carcinoma (EMC) and its histologic variants; type II endometrial cancer includes serous carcinoma, clear cell carcinoma, and carcino sarcoma. Uterine serous carcinoma (ESC), type II, accounts for approximately 10% of cases, whereas EMC, type I, encompasses bout 80% to 85% of cases. Clear cell carcinoma and other rare forms of endometrial carcinoma comprise the few remaining cases. Type I and type II endometrial carcinomas are considered biologically distinct disease entities, characterized by their divergent histology, molecular genetics, tumor genesis, and clinical behavior. Different patterns of molecular alterations are now thought to underlie the pathogenesis and/or progression of type I and type II uterine carcinomas. For example, the most common genetic alterations in EMC include microsatellite instability, mutations of PTEN, b-catenin, PIK3CA, and K-ras. In contrast, in the case of ESC, p53 mutations are common and ERBB2 (formerly HER2) overexpression or amplification is also frequently seen. Clinically, ESC has a higher propensity for lymphovascular invasion and intraperitoneal as well as extra-abdominal spread than EMC. During presentation, approximately 40% to 70% of women with ESC will have disease beyond the uterus. Accurate diagnosis of tumor type in endometrial biopsies/curetting specimens is critical for patient management. Tumor classification in endometrial adenocarcinoma based on histology and immunohistochemistry has some limitations, particularly in lesions with mixed epithelial differentiation or vague morphology. Moving forward, development of molecular biomarkers may be the next step in refining our classification of these tumors in general and on a case-by-case basis (Wei JJ, Painta Al, Keh P. Histologic and Immunohistochemical Analyses of Endometrial Carcinomas. *Arch Pathol Lab Med*. 2013; 137: 1574-1583).

PAIN AS A LATE EMOTIONAL REACTION - CLINICAL RESEARCH EVALUATING THE PSYCHOSOCIAL EXPRESSION OF PAIN DISORDER IN PREOPERATIVE AND POSTOPERATIVE PERIOD (Abstract) **Aim:** A comparative analysis of the influence of psychosocial factors on pain perception in preoperative and postoperative period in patients scheduled for abdominal surgery. **Material and methods:** A psychological assessment was performed in 50 patients without psychiatric history scheduled for abdominal surgery. The verbal expression of pain, intensity of anxiety, catastrophizing level, and the interpersonal relationships were assessed. **Results:** Surgery has a powerful effect on the perception of pain intensity. Postoperatively patients perceive significantly lower pain than in the preoperative period (p=0.001). In the postoperative period the patients mainly use emotional and evaluative verbal expressions (p=0.000 and p=0.000, respectively), have a high index of anxiety (p=0.000), adopt a higher level of coping self-statements (p=0.002), and have a higher level of perception of others (family, friends) (p=0.005). **Conclusions:** In patients undergoing surgery, surgery affects their psyche, triggering a series of events that can have psychological effects on pain intensity, doctor-patient relationship, postoperative complications, and shortening of recovery time. **Keywords:** ALGIC DISORDER, PAIN PERCEPTION, PSYCHOSOCIAL FACTORS, PREOPERATIVE PHASE, POSTOPERATIVE PERIOD

Surgery is the most fascinating and dramatic specialty of medicine, with a large emotional charge for both the surgeon and patient, often at the edge of survival. Surgical act depends not only on lucid thinking and unerringly movement of surgeon hand, but also on how the patient reacts to the surgical act, or later on how he recovers from the body changes (even if they are lifesaving) caused by surgical maneuvers. More and more studies on patients with various types of surgery show that psychical factors and psychological implications play an important role in the dynamics of doctor-patient relationship and in postoperative course (1, 2, 3, 4).

There are many opinions in favor of replacing the technicist-somatization mentality with psychosomatics, recognizing that psychological characteristics are present in most surgeries: the novelty of the situation created by the presence of lesion or dysfunction to be corrected by the surgeon (with special effects on the surgeon) and anxiety (extreme for patient, but great for surgeon) generated by the surgical risks that often target patient survival. The aim of this research was to study how psycho-

logical factors influence the surgical act and patient mental state.

MATERIAL AND METHODS

Patients. This research was carried out in 50 inpatients scheduled for abdominal surgery, was approved by the Ethics Committee of the Iaşi „Dr. Iacob Czihac" Emergency Military Hospital, and was conducted in conformity to the Declaration of Helsinki.

The inpatients enrolled in this research had predominantly abdominal pain, and were scheduled for abdominal surgery. Exclusion criteria included prior abdominal surgery and psychiatric history.

Patient examination. All patients underwent a clinical interview: the McGill Pain Questionnaire (5), Coping Strategies Questionnaire (6), Anxiety Symptom Questionnaire (7), Pain Catastrophizing Scale (8) and West Haven-Yale Multidimensional Pain Inventory (9).

The clinical interview was designed to highlight: non-verbal indicators of pain, family history, description, evaluation, frequency and persistence of present pain, memory of pain, pain behavior, perceived attitudes of others, self-assessment of pain tolerance, types of pain therapy, indicating the body areas affected by pain so far, beliefs about pain, involvement in daily activities, family relationships, medical information about pain.

The McGill Pain Questionnaire is a self-report questionnaire that allows individuals to give their doctor a good description of the quality and intensity of pain that they are experiencing. The McGill Pain Questionnaire consists primarily of 3 major classes of word descriptors – sensory, affective and evaluative – that are used by patients to specify subjective pain experience. It also contains an intensity scale and other items to determine the properties of pain experience. The 3 major measures are: 1. pain rating index, based on two types of numerical values that can be assigned to each word descriptor, 2. number of words chosen; and 3. present pain intensity based on a 1-5 intensity scale.

The Coping Strategies Questionnaire (CSQ) consists of 50 items assessing patient self rated use of cognitive and behavioral strategies to cope with pain. It comprises six subscales for cognitive strategies (ignoring pain, reinterpretation of pain, diverting attention, coping self statements, catastrophizing, praying/hoping) and two subscales for behavioral strategies (increasing activity levels and increasing pain behaviors). Each coping strategy subscale consists of six items measured with a numerical rating scale ranging from 0 (never do that) to 6 (always do that) indicating how frequently the strategy is used to cope with pain. An additional two single item questions each with a scoring range of 0–6 are used as effectiveness ratings of control over pain and ability to decrease pain.

The Anxiety Symptom Questionnaire (LWASQ), developed to measure the level of anxiety, consists of 36 items, which include somatic, cognitive and behavioral components of anxiety: 16 somatic items (physical manifestation of anxiety), 9 behavioral items (avoidance of social situations), and 11 cognitive items (the tendency to worry and ruminate). The scale ranges from zero (never) to eight (extremely often).

The Pain Catastrophizing Scale (PCS) is a 13 item scale, with each item rated on a 5–point scale: 0 (not at all) to 4 (all the time), broken into three subscales: magnification, rumination, and helplessness. The scale was developed as a self-report measurement tool that provided a valid index of

catastrophizing in clinical and non-clinical populations, a reliable and valid measurement tool for catastrophizing. From a clinical perspective, the PCS is useful in identifying individuals that may be more susceptible to high distress responses from aversive medical procedures such as chemotherapy or surgery.

The West Haven-Yale Multidimensional Pain Inventory (WHYMPI) is designed to provide a brief, psychometrically-sound, and comprehensive assessment of the important components of the chronic pain experience. The WHYMPI is a 52-item, 12-scale inventory that is divided into three parts. Part I includes five scales designed to measure important dimensions of the chronic pain experience including; 1. perceived interference of pain in vocational, social/recreational, and family/marital functioning, 2. support or concern from spouse or significant other, 3. pain severity, 4. perceived life control, and 5. affective distress. Part II assesses patients' perceptions of the degree to which spouses or significant others display Solicitous, Distracting or Negative responses to their pain behaviors and complaints. Part III assesses patients' report of the frequency with which they engage in four categories of common everyday activities; Household Chores, Outdoor Work, Activities Away from Home, and Social Activities. In addition to the individual scale scores, a General Activity scale score, obtained from the combination of all four activity scale scores, has been recommended for some purposes. Patient responses to WHYMPI items are given using a 7-point numeric scale.

Follow-up. Psychological evaluation of patients was performed at surgeon's request, being focused on their behavior during surgical preparation. Postoperative assessment was done one month after surgery, the mandatory postoperative follow-up (randomized study).

Main outcome measures. The primary outcome measure was emphasizing pain perception: sensory, affective and evaluative pain experience; pain rating index; the number of words chosen; and the present pain intensity. The secondary outcome measures included determination of: anxiety levels, catastrophizing levels, coping types, and components of chronic pain experience.

Statistical analysis. The continuous variables were tested using Student's tests (normally distributed data). The statistical analysis was performed using *SPSS 13.0* statistical software.

RESULTS

Regarding the perception of pain by patients in preoperative and postoperative periods, this research did not show statistically significant gender, age and education differences in pain threshold $p < 0.05$.

The total index measuring patient pain after surgery was significantly lower ($p=0.001$) than the total index measuring patient pain before surgery. The sensory component of patient pain after surgery was significantly lower ($p=0.000$) than the sensory component of the patient pain prior to surgery. The affective component of patient pain after surgery was significantly higher ($p=0.000$) than the affective component of patient pain before surgery. The evaluative component of the patients pain after surgery was significantly higher ($p=0.000$) than the evaluative component of patient pain before surgery. Generalized anxiety level of patients after surgery is significantly higher ($p=0,000$) than the level of generalized anxiety in patients prior to surgery. The generalized anxiety level of patients after surgery was significantly higher ($p=0.000$) than the level of

generalized anxiety prior to surgery. The level of reactions of others (family, friends) to patient complaints of post-surgery pain was significantly higher (p=0.000) than the level of reactions of others (family, friends) to patient complaints of preoperative pain.

DISCUSSION

This research is relevant because it demonstrates how verbal expression of pain, emotional disposal, cognitions and interpersonal relationships vary by surgery time. A comparative analysis of preoperative and postoperative pain perception indicates a significantly less overall postoperative pain. This result is inconsistent with studies that claim that post-surgical pain intensity index increases (10, 11, 12). The lower intensity of the perceived post-surgery pain can be interpreted psychologically by the quasi-objective relationship between pain caused by somatic disease, surgery, perceptual environment (due to anesthesia and analgesics the patient does not experience any pain) and expectations of healing - the patient thinks he regains health.

Postoperatively patients describe less sensory pain than preoperatively. The sensory discriminative dimension reflects the somatic aspect of pain. Preoperative pain is considered an acute pain which initiates protective physiological mechanisms in response to somatic injury. Postoperatively patients do not feel threat to the body, and therefore describe less sensory pain than in the preoperative phase. Surgery produces changes in bodily sensations and mental state; pain is interpreted by the patient as having different clinical significances, as an indicator of disease or of healing, and therefore patients describe less sensory pain postoperatively than preoperatively.

Patient language is an indicator of mental state; thus post-surgery patient is dominant in affective and evaluative verbal expressions.

Postoperatively patients perceive more emotional pain than preoperatively, describing emotional pain one month after surgery indicates that patients still live under the "threat" of the disease, and that the pace of health progress, the recovery, is inconsistent with the expectations.

In postoperative period patients perceive more evaluative pain than patients in preoperative phase. Surgical act exposing the body to a traumatic situation is mind-boggling in patients with no previous surgical experience, and although accepted as necessary, it triggers attitudes, associations, thoughts, and significances about the meaning of pain, disease, and even life. In the preoperative period the patient cannot categorize and analyze the significance and consequences of surgery (13). After surgery, the information is organized, analyzed and has an effect on patient depending on the differences between preoperative and postoperative expectations. Assessment of pain perception in the preoperative and postoperative periods and of how the intensity and quality of pain is described may be indicators of post-traumatic stress disorder.

Generalized anxiety level in post-surgery patients is significantly higher, because of physical discomfort and possible functional impotence, but also because the patient recalls the dangers he went through and the fear that these, or other similar ones, will happen again.

If in the preoperative period anxiety is sometimes controlled pharmacologically or psychotherapeutically by the intervention team, the postoperative patient is a "solved problem" and, therefore, many patients return to hospital or continue clinically investigations, becoming likely to have iatrogenic stress.

The level of coping self-statements is significantly higher after than before surgery (14). Repressed fear and emotions before surgery are expressed postoperatively, and the use on this method of coping signifies the need for a patient to control pain, as coping self-statements are active coping, "everything is OK". Post-surgical patient adopts an active coping and is responsive to how "pain" will influence family relationships. This active coping has a variable degree of stability and qualitative value likely to resist or succumb to the action of psychological and traumatic factors on social and family life.

The level of reactions of others (family, friends) to patient complaints of pain after surgery is significantly higher than the level of reactions of others (family, friends) to patient complaints of pain before surgery (15, 16). Family behavioral and attitudinal reactions and support provided during post-surgery favor recovery and reintegration in the social and professional life.

CONCLUSIONS

Surgery affects the psyche of the patient undergoing surgery, triggering a series of events that can have psychological effects on pain intensity, doctor-patient relationship, post-surgery complications, and shortening of recovery time.

These results suggest that the integration of the psychosomatic concept in surgical practice, without denying the professionalism of the surgeon, can contribute to increased surgery success rate; good knowledge of psychological elements involved in the dynamics of surgery can be used for a successful surgical optimization.

IMAGING EVALUATION OF JOINTS PATIENTS WITH SYSTEMIC LUPUS ERYTHEMATOSUS

A group of researchers conducted a study that assessed the prevalence of joint involvement in patients with systemic lupus erythematosus (SLE) by means of clinical assessment, joint US and MRI and evaluated the sensitivity and specificity of physician evaluation of joint involvement. At enrolment, patients underwent a complete physical examination including a 44-joint count, and hand deformities were scored. On the day of enrolment, each patient underwent a non-dominant hand-wrist ultrasound (US) examination and a non-dominant hand-wrist MRI study without contrast injection. By physician examination hand or wrist involvement was diagnosed in 23.5%. At least one pathological finding was revealed by US examination at wrist and/or hand joints in 55%. They found a low sensitivity (46.5%) with high specificity (93.2%) of the physician assessment for the evaluation of joint involvement. The MRI imaging showed at least one erosion in 47.3% patients at the hand and in 98.9% at the wrist. The authors concluded that the physicians tend to underestimate the severity of joint involvement in SLE, the US assessment showed a high prevalence of joint and tendon involvement, and the MRI evaluation showed a high prevalence of damage, suggesting that joint involvement in SLE could be more severe than expected. (Mosca M, Tani C, Carli L et al. The role of imaging in the evaluation of joint involvement in 102 consecutive patients with systemic lupus erythematosus *Autoimmun Rev*. 2014 Aug 23.[Epub ahead of print]. PMI 2518324

GONIOSCOPIC FINDINGS IN PATIENTS WITH ACUTE CENTRAL/HEMICENTRAL RETINAL VEIN OCCLUSIONS (Abstract) **Obiectives:** To evaluate prospectively the gonioscopic findings and their changes during a 3-year follow-up period in patients with acute central/hemicentral retinal vein occlusions (C/HRVOs). **Material and methods:** A comprehensive ophthalmological examination of both eyes including static and dynamic gonioscopy as well as ocular biometric measurements was performed in 57 patients with acute C/HRVOs. The angle configuration and its changes, the axial length of the globe, the anterior chamber depth and the corneal thickness were assessed. **Results:** 12 C/HRVO patients presented with narrow drainage angles (≤ 20º) and 45 had normal angles (>20º). Ocular globes with narrow angles had axial length and anterior chamber depth significantly smaller as well as cornea thickness significantly greater than the eyes with normal angles. Out of the 12 patients with narrow angles, 6 cases had primary angle closure suspect (PACS), 5 cases had primary angle closure (PAC) and one case primary angle closure glaucoma (PACG). 3 of the 6 PACS patients progressed to PAC in the 6th, 10th, and 18th months of the follow-up period. From the 8 PAC cases existing during the whole study interval, one case progressed to PACG during the 24th month of the folow-up interval. **Conclusions:** In the context of an ocular globe having its size significantly smaller than the normal eye, narrow angle may represent a local risk factor predisposing to C/HRVO. Intermittent episodes of angle closure may contribute by increasing the intraocular pressure to the occurrence of C/HRVO as well to the progression of the gonioscopic configuration from PACS to PAC and from PAC to PACG.
Keywords: CENNTRAL/HEMICENTRAL RETINAL VEIN OCCLUSION, PRIMARY ANGEL CLOSURE SUSPECT, PRIMARY ANGLE CLOSURE, PRIMARY ANGLE CLOSURE GLAUCOMA

Gonioscopy is considered the current reference-standard examination whose purpose is to visualize the anterior chamber angle as completely as possible. It enables identification of the iridotrabecular contact and is the only examination method that is able to differentiate appositional from synechial angle closure (1, 2).

Closure of the anterior chamber angle in central retinal vein occlusion (CRVO) may appear as a primary (in predisposed eyes) or secondary event; the latter case is caused

either by neovascularization of the angle (3) or by a marked anterior displacement of the lens-iris diaphragm due to abnormal accumulation of blood or edema fluid in the posterior segment of the eye, a non-rubeotic state having some similarities to malignant glaucoma (4, 5).

The aim of this study is to evaluate prospectively the gonioscopic findings and their changes during a 3-year follow-up period in patients with acute central/hemicentral retinal vein occlusions (C/HRVOs).

MATERIAL AND METHODS

Patient population. The study was carried out in 57 unilateral acute C/HRVO patients, was approved by the University "Grigore T. Popa" Iaşi Ethics Committee and conformed to the tenets of the Declaration of Helsinki.

The patients enrolled in the study had a unilateral CRVO or hemicentral retinal vein occlusion (HRVO) with duration of symptoms of venous occlusive event of < 1 month. Exclusion criteria included prior tratament (filtering surgery, corneal transplantation, pars plana vitrectomy, or photocoagulation), aphakia or pseudophakia and any vascular retinal disorders in the study eye or age-related macular degeneration (e.g. drusen, geographic atrophy and neovascular form) in any of the 2 eyes.

Patient examination. All patients underwent a comprehensive baseline ophthalmological examination of both eyes. Best corrected visual acuity (BCVA) score was determined using the Early Treatment Diabetic Retinopathy Study (ETDRS) protocol (Snellen equivalent plus ETDRS letters) (6). Careful testing of the visual field was performed by means of the Goldmann perimeter using I2e, I4e and V4e isopters. In case of suspicion of concomitant primary glaucoma, the Humphrey standard automatic perimetry (Humphrey Instruments, Inc, San Leandro, California; model 720i; programme SITA FAST, 30-2) was used. Biomicroscopic examination was carried out with dilated and nondilated pupil. Thorough evaluation of the ocular fundus was performed with direct and indirect ophthalmoscopy and, if needed, using a contact lens. Fluorescein angiography was focused on both disc and macula during early examination times, on middle retinal periphery of each quadrant during intermediate phases and again on disc and macula in the late examination times. Intraocular pressure (IOP) was determined by using the Perkins applanotomometer and was adjusted for the corneal thickness. A scan ultrasonic ocular biometry was undertaken with Alcon Ultrascan Imaging System (Alcon, Inc, Forth Worth, Tx). The examination included following determinations: the axial length of the eye, the anterior chamber depth and the lens thickness. Optical Coherence Tomography (Stratus OCT; Carl Zeiss Meditec, Dublin, CA, USA) was used for evaluating the macular morphology and thickness, the optic disc and the retinal nerve fiber layer (RNFL). Gonioscopy was performed with the patient sitting at a slit-lamp, at high magnification (16 x) in a dark room using a two-mirror Goldmann gonioscopic lens. Beside the usual technique of the static gonioscopy, we used also dynamic gonioscopy.

Treatment and follow-up. The treatment applied to acute C/HRVO patients consisted of intravitreal bevacizumab (IVB) (Avastin; Genentech Inc., San Francisco, CA) injections in a dose of 2.5 mgr per injection until a stabilization of the BCVA score, lasting at least 6 months was

achieved. Patient follow-up was carried out every two months during the first year and every 6 months thereafter within the next two years.

Diagnostic criteria. A) Normal (not occludable) anterior chamber angle (> 20 grade) (7): The posterior third of the trabecular meshwork (usually pigmented) is visible for more than 180 degrees, on static gonioscopy with the eye in the primary position. This configuration involves both eyes. B) Narrow drainage angle (≤ 20 grade) (2, 8, 9): Non-visibility of the posterior trabecular meshwork for ≥ 180 degrees of the angle circumference on non-indentation gonioscopy with the eye in the primary position. It has two variants, namely, moderately narrow angle (angular width 15-20º) and extremely narrow angle (≤ 10º). This configuration involves both eyes. C) Primary angle closure suspect [PACS] (1, 7), namely an eye in which appositional contacts between the peripheral iris and the posterior trabecular meshwork is considered possible/probable: -Narrow drainage angle, IOP below 22 mmHg, no peripheral anterior synechiae (PAS) in the angle, and without glaucomatous optic neuropathy (GON); -Absence of the ocular pathology, that can induce PAS formation (uveitis, neovascularization, trauma, surgery). D) Primary angle closure [PAC] (7, 9, 10, 11, 12, 13): -Narrow drainage angle; -Excluded were eyes in which narrow angles or shallow anterior chambers were thought to be secondary to the other ocular conditions, such as, lens abnormalities, chronic uveitis, trauma, rubeosis iridis or retinopathy of prematurity; -Optic disc and visual field definitely considered as nonglaucomatous; -The presence of at least one of the following features indicating that trabecular obstruction by the peripheral iris occurred: a) PAS; b) IOP > 21 mmHg; c) Excessive pigment deposition on the trabecular meshwork surface, especially superior; d) Ischemic sequelae of acutely raised IOP (distorsion of the radially orientated iris musculature, iris stromal atrophy, dilated nonresponsive pupil, focal necrosis of lens epithelium causing glaucomfleken) (1) ; e) Clear history of clinical signs or symptoms such as headaches, congestion, blurred or halo vision, corneal edema or a mid-dilated pupil, consistent with sudden IOP rise; f) Evidence of a surgical peripheral iridotomy; g) Dark room provocation test giving a rise in IOP of ≥ 8 mmHg from baseline. E) Primary angle closure glaucoma [PACG] (1, 7, 9, 13) :- Presence of PAC; - Consistent visual morbidity; - Typical GON (1,10.14) is characterized by irreversible structural and/or functional glaucomatous lesion, indistinguishable from the primary open angle glaucoma; structural glaucomatous damage includes aquired characteristic progressive optic neuropathy (eg optic disc cupping; narrowing the area of neuroretinal rim; localized “notch”; disc hemorrhages; newly appeared asymmetry in the cup/disc ratio ≥ 0.2 between both eyes; change in the cup/disc ratio > 0.2) that could be documented alongside the follow-up, and/or changes of the RNFL (diffuse or localized defects); functional glaucomatous damage comprises reproducible characteristic changes of the visual field (retinal nerve fiber bundle defects) corresponding to the optic disc lesion; - Atypical GON (1) occurs after an acute symptomatic episode of angle closure and presents with a pale but flat optic disc, suggesting an anterior ischemic optic neuropathy.

Main outcome measures. The primary outcome measure was emphasizing the gonioscopic configuration of the anterior

chamber angle in patients with C/HRVOs. The secondary outcome measures included: determination of the axial length of the eye, the anterior chamber depth as well as the lens and the cornea thicknesses; the cumulative prevalences of the PACS, the PAC and the PACG; the progression rates from PACS to PAC as well as from PAC to PACG.

Statistical analysis. The continuous variables were tested using Student's tests (normal distributed data) and both the Man Whitney U and the Wilcoxon tests for non-parametric distributions. Categorical data were analyzed by means of the Person chi-square test and the Fisher exact test. Cumulative prevalence calculation was made by using the Kaplan-Meier estimate. The statistical analysis was performed using *SPSS* statistical software (version 16.0) and *Epi-Info 2000*.

RESULTS

From total, 12 C/HRVO patients presented with narrow anterior chamber angles (≤ 20º) and 45 patients had normal drainage angles (>20º) (tab. I). Venous occlusions in patients with narrow angles occurred at an age significantly greater (p=0.001) than those in patients with normal angles.

TABLE I

Demographic and clinical baseline characteristics in 57 patients with central / hemicentral retinal vein occlusion

	Anterior chamber drainage angle			**Total**
Variables	**Narrow (n = 12)**	**Normal (n = 45)**	**p-value**	**(n = 57)**
Age (years)

CRVO = central retinal vein occlusion; HRVO = hemicentral retinal vein occlusion

Biometric measurements emphasized an axial length of the ocular globe significantly smaller (21.69±0.93 mm; p=0.004) and an anterior chamber depth significantly lower (1.8±0.09 mm; p=0.0009) in patients with C/HRVOs having a gonioscopic configuration of narrow angle compared with those with a normal angle configuration (22.69±0.94 mm and 2.58±0.55 mm, respectively). The cornea thickness was significantly great (p=0.0009) in patients with narrow angles (0.6 ± 0.02 mm) *vs.*

those with normal angles (0.54 ± 0.02 mm).

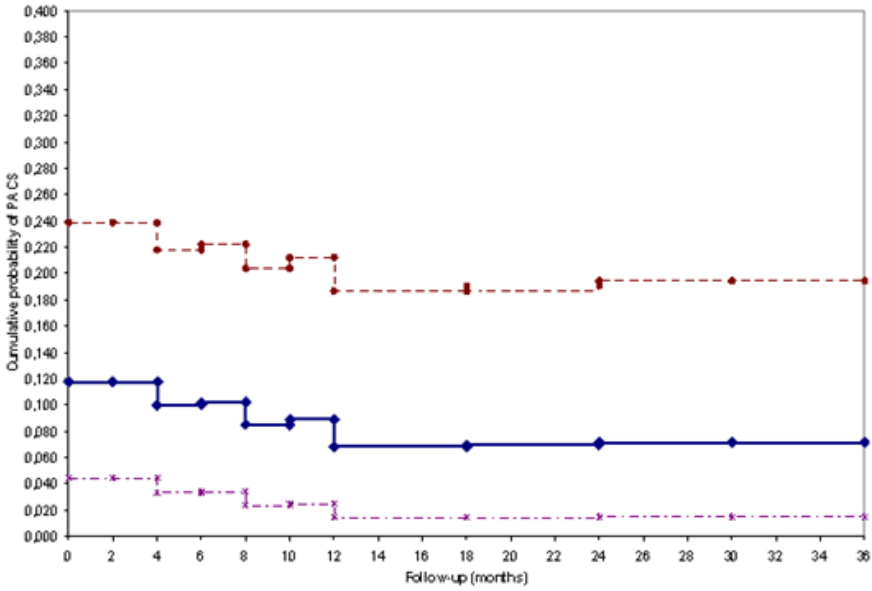
Three possible clinical forms of angle closure status existed at the beginning of the study in the 12 patients with venous occlusions having narrow angles (tab. II), namely PACS in 6 cases, PAC in 5 cases and PACG in one case.

TABLE II

Clinical forms of angle-closure status in 12 patients with central/hemicentral retinal vein occlusion having narrow drainage angles

Angle-closure status	PACS	PAC	PACG	Total
Baseline (n)	6	5	1	12
Final (n)	3	7	2	12

PACS = primary angle closure suspect; PAC = primary angle closure; PACG = primary angle closure glaucoma

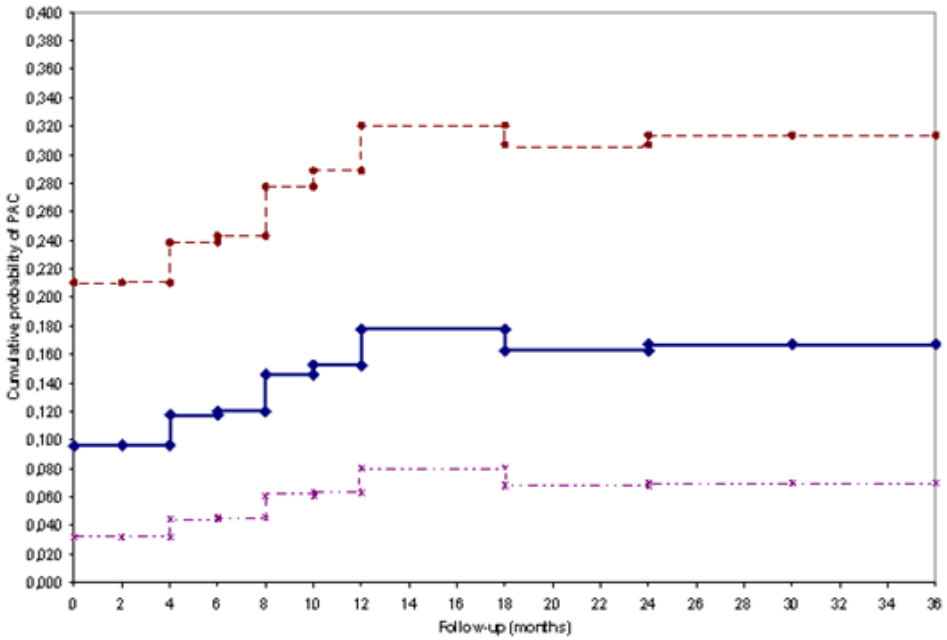


Follow-up	2	4	6	8	10	12	18	24	30	36
No at risk	51	51	50	49	47	45	44	43	42	42
PACS	6	0	-1	0	-1	0	-1	0	0	0
Censored	0	0	0	1	1	2	0	1	1	0

Fig. 1. The Kaplan-Meier estimate of the cumulative prevalence of the primary angle closure suspect over the entire course of the study in 57 central/hemicentral retinal vein occlusion patients. Patients at risk are those who did no present primary angle closure suspect at the beginning of the study. Patients who were lost before the end of the study were censored from the last completed visit. The dotted lines represent the upper and lower bounds of the 95% confidence interval.

Peripheral laser iridotomy was performed in 4 out of the five patients with PAC and trabeculectomy in the patient with PACG. One patient with PAC refused laser

intervention. 3 of the 6 PACS patients (50%) progressed to PAC in the 6-th, 10-th and 18th months of the follow-up period (16.6% per year), following some asymptomatic episodes of angle closure (unilateral progression in the occlusion eye). Peripheral laser iridotomy was performed in all three patients. So, the cumulative prevalence of PACSs decreased from 11.76% (95% confidence interval (CI), 4.44-23.87) to 7.14% (95% CI 1.5-19.43) (fig. 1) while the cumulative prevalence of PAC increased from 9,6% (95% CI, 3.2-21.03) to 16.6% (95% CI, 6.97-31.36) (fig. 2).

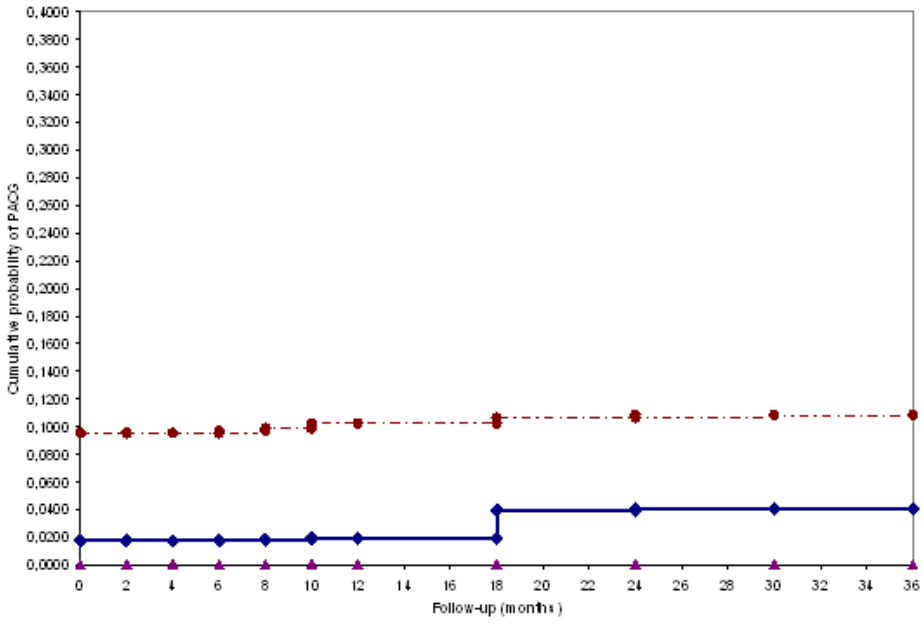


Follow-up	2	4	6	8	10	12	18	24	30	36
No at risk	52	52	51	50	48	46	45	43	42	42
PAC	5	0	1	0	1	0	1	-1	0	0
Censored	0	0	0	1	1	2	0	1	1	0

Fig. 2. The Kaplan-Meier estimate of the cumulative prevalence of the primary angle closure over the entire course of the study in 57 central/hemicentral retinal vein occlusion patients. Patients at risk are those who did not present primary angle closure at the beginning of the study period. Patients who were lost before the ends of the study were censored from the last completed visit and those who died were censored at their date of death. The dotted lines represent the upper and lower bounds of the 95% confidence interval.

From the 8 cases with PAC existing during the whole study period, only one (12.5%) progressed to PACG during the 24th month of the follow-up period (4.16% per year) follow-

ing an acute episode of angle closure (unilateral progression in the occlusion eye). This patient (a female aged 74 years) is the one who refused laser treatment during the PAC status and who declined again the surgery during PACG status. She exhibited a pale but flat optic disc with altitudinal visual field defects closely resembling anterior ischemic optic neuropathy. So, the cumulative prevalence of PACG increased from 1.78% (95% CI, 0.045-9.552) to 4.08% (95% CI, 0.05-10.85) (fig. 3).



Follow-up	2	4	6	8	10	12	18	24	30	36

PACG	1	0	0	0	0	0	0	1	0	0
Censored	0	0	0	1	1	2	0	1	1	0

Fig. 3. The Kaplan-Meier estimate of the cumulative prevalence of the primary angle closure glaucoma over the entire course of the study in 57 central/hemicentral retinal vein occlusion patients. Patients at risk are those who did not present primary angle closure glaucoma at the beginning of the study period. Patients who were lost before the ends of the study were censored from the last completed visit and those who died were censored at their date of death. The dotted lines represent the upper and lower bounds of the 95% confidence interval.

DISCUSSION

An important ascertainement of this study is the great incidence (12 cases; 21%) of the narrow angles (≤ 20º) in patients with C/HRVOs, namely moderately narrow angles (15-20º) in 7 cases and extremely narrow angles (≤ 10º) in 5 cases. This frequency is evidently greater compared to that existing in the general population [between 2% (15) and 14.8% (16)].

The statistically significant difference between the mean age of the venous occlusion patients with narrow and normal angles (tab. I) caused us to suspect the possible role played by an advanced age in the occurrence of such high percentage of the narrow angles. The narrowing of the anterior chamber angle appears to be a function of normal aging (11). With advancing in age, an angle may become occludable.

In the eyes with narrow angles of our series, the ocular biometric measurements were totally different from those existing in the ocular globes with normal angles (> 20º). So, the axial length of the globe and the anterior chamber depth were significantly smaller and the cornea thickness was significantly greater in eyes with narrow angles compared to eyes with normal angles. This configuration of the ocular globe having the size of the anterior segment smaller than the average may represent a local risk factor predisposing to CRVO, especially for an ischemic form of the venous occlusions. The changes mentioned are not the result of the occlusion but an expression of the constitutional factors with inherited characteristics. Shorter axial length may also indicate crowded posterior segment. In such eyes, retinal vein and artery that share the same adventitial sheath are more crowded and impaired as they pass through the *lamina cribrosa*; this status may narrow the lumen of the vein with all its subsequent consequences, namely, decrease of the blood flow, increase of the blood viscosity and local turbulence that could cause thrombosis (17).

At the beginning of the study, 6 cases of CVROs with narrow angles were diagnosed as having closure of the angle, namely 5 cases with PAC and one case with PACG (tab. II). These patients were experiencing a history of symptoms of intermittent IOP rises as a consequence of the angle closure. After reversing such an episode, patients complained about the persistence of blurred vision, which determined them to have an ophthalmological examination. On this occasion the ophthalmologist ascertained the existence of the venous occlusion. In these cases, the episodes of ocular hypertension due to angle closure may have triggered the occurrence of the venous occlusions (18). Increasing the IOP induce compression, stretching, deformation, and backward displacement of the lamina cribrosa that secondarily may distort the vein (19). The collapse of the retinal vein due to compression and subsequent endothelial lesion with intimal proliferation caused the vein to occlude at the level of the lamina cribrosa.

Progression from the PACS to PAC occurred in 3 eyes with CRVOs out of the 6 cases with PACS being present at the entry (50%; 16.6% per year). This incidence per year of progression from PACS to PAC is greater than that existing in the general population (22%; 4.4% per year) (7), which plead in favor of the fact that CRVO may represent a risk factor for the progression. The progression from PAC to PACG appeared only in a single eye with CRVO out of the 8 PAC cases existing during the whole study period (12.5%; 4.16% per year); so, the incidence per year of progression from PAC to PACG is consistent with that being present in the general population (28.57%; 5.7% per year) (13).

The successive episodes of angle closure after venous occlusion occurrence may account for the progressions ascertained. Increased thickness of the lens accompanied by a change in its shape due to slackening of the zonules causing the lens to

move forward (15), represent the main growth and dynamic factors that, in the presence of the constitutional ones with inherited characteristics, determine decreasing the angular width as the age advances (7, 15, 20). All of these factors combine to hasten the closure of the angle with advancing in age.

The main limitation of the study was the lack of a control group recruited from the general population of the same location in which all the determinations should have been done, namely the evaluation of the incidence of different angle configurations as well as of the cumulative prevalence of the varied clinical forms of the angle closure and their progressions.

CONCLUSIONS

From our study we can conclude that the narrow angle in the context of an ocular globe having its size significantly smaller than the normal eye may represent a local risk factor predisposing to C/HRVO. Intermittent episodes of angle closure may contribute to the occurrence of the C/HRVO as well as to the progression of the gonioscopic changes.

ELECTRONIC MEDICAL RECORDS - AN IMPERFECT SYSTEM WITH GOOD RESULTS FOR IDENTIFYING PATIENTS WITH A COMMON PHENOTYPE

The objective of this review was to summarize literature describing approaches aimed at automatically identifying patients with a common phenotype. The authors performed a review of studies describing systems or reporting techniques developed for identifying cohorts of patients with specific phenotypes. Every full text article published in (1) *Journal of American Medical Informatics Association*, (2) *Journal of Biomedical Informatics*, (3) *Proceedings of the Annual American Medical Informatics Association Symposium*, and (4) *Proceedings of Clinical Research Informatics Conference* within the past 3 years was assessed for inclusion in the review. Only articles using automated techniques were included. The identification of patients who satisfy predefined criteria from a large population in an institution has numerous use cases, including clinical trial recruitment, outcome prediction, survival analysis, and other kinds of retrospective studies. However, the process of distinguishing these patients on the basis of their patient records can be extremely time-consuming and challenging depending on the complexity of the criteria. This is because the data matching these criteria are buried within multiple documents and across multiple data points in the electronic health record (EHR) of a patient. Some data, such as laboratory results, medications, and diagnoses, have a structured format. The ability to extract meaningful pieces of information from the EHR and consolidate them into a coherent structure would provide great value for automatically identifying patient cohorts that satisfy complex criteria. Studies in this review addressed different diagnoses as the phenotype of interest. A large number of papers focused on diabetes, cancer, heart failure, rheumatoid arthritis, or cataract. A few studies described generic methods that could be applied to multiple diagnoses. Several papers addressed identification of adverse drug events. Some studies also analyzed genomic data of a predetermined phenotype to gain insight into other phenotypic properties of the same cohort. Authors have developed a top of the first 10 phenotypes of interest. Although cancer has been reported as a generic phenotype, there were 12 types of cancer (with breast cancer being most prevalent) studied in seven articles. Congestive heart failure and heart failure were counted as the same phenotype. Similarly, hypertension and resistant hypertension were considered to be one phenotype. Some articles also considered other observable characteristics such as smoking status and obesity among patients. Pneumonia and a variety of other infectious diseases were studied. This review is not without limitations, especially for the vagueness of the term phenotyping, meaning that there is no exhaustive search strategy for retrieving appropriate articles across the entire available body of biomedical literature. However, because of the venues considered and the recent popularity of this topic, this review is representative of past and present efforts in this domain. RAD51 OVEREXPRESSION AND RESISTANCE TO GENOTOXIC AGENTS. A STUDY IN THE FISSION YEAST SCHIZOSACCHAROMYCES POMBE **(Abstract): Background:** Many cancer cell lines have been found to overexpress the recombinase Rad51. The overexpression is associated with increased invasive potential and resistance to DNA-damaging therapeutic agents. This has been attributed to an increased capacity of cells over-expressing Rad51 to repair DNA lesions or to a genetic stabilization of the genome. **Aim:** As the explanations are somewhat controversial, we attempted to reproduce overexpression in the unicellular eukaryote *Schizosaccharomyces pombe* to have a simpler tool to study the problem of Rad51 overexpression and its induced resistance to DNA-damaging agents. **Methods:** We used the *nmt1* promoter inserted upstream of *rad51*gene to induce its overexpression and studied the phenotype of the transformed strain, especially its sensitivity to camptothecin and hydroxyurea. **Results:** We found that overexpression induced sensitivity to the two drugs even when it was associated with the deletion of a recombination mediator *rad22/rad52* gene. However, when overexpression was associated with the deletion of the helicase-encoding *fbh1* gene, the sensitivity to camptothecin was diminished. **Keywords**: RAD51 OVEREXPRESSION, HOMOLOGOUS RECOMBINATION, RAD22, FBH1.

Rad51 protein is a central player involved in repair of the DNA double-strand breaks by homologous recombination. Rad51 is a component of the recombination nucleo-protein filament: a DNA single stranded overhang (resulting from the end processing of a double-stranded end) wrapped around a Rad51 polymer in a helical manner. The nucleofilament invades the double helix of a sister chromatid or a homologous chromosome forming the so called D loop, a structure that initiates homologous recombination (1). Rad51 is essential in mammalian cells; mouse embryos carrying deletion of the *rad51* gene are unviable (2).

Publications issued after 2002 have reported a Rad51 overexpression in many (over 50%) of human cancers (3). The overexpression exceeds about 2-7 fold the level of the expression in normal parental cells, in terms of the Rad51 protein amount. It is due to an excessive transcription of the gene (4). Some activating influence over the genes promoter occurs. In a series of 13 cancer cell lines, the activity of the *rad51* promoter was tested with a different gene reporter (luciferase) and a dramatically increased level of the reporter protein occurred (several hundred fold) in cancer cells when compared to normal fibroblasts (5). In the same cell lines the

Rad51 mRNA and protein were increased only about six fold, which means that a limiting action on the transcript's level also occurs. The overexpression confers either increased invasive potential and/or increased resistance to genotoxic agents used for cancer therapy (4,6).

Overexpression has *causes* and *consequences*. Both causes and consequences are important to be known for cancer prevention and therapy. A way of discovering them is to look for genome modifications accompanying the Rad51 overexpression. Some of these are the ones leading to losses of function of p53, BRCA1, BRCA2 and gain of function of the oncoprotein BCR/ABL (3).

p53 is a well known tumor suppressor. It is a transcription factor important for the regulation of cell cycle. p53 is a negative regulator of the *rad51*gene expression by directly inhibiting its transcription (6). BCR/ABL is an activator of the *rad51* expression through STAT5-dependent transcription of *rad51* and inhibition of Rad51 protein cleavage by caspase-3 (7). BRCA1 and 2 are proteins involved in homologous recombination like Rad51 itself (8). Their loss-of-function mutant alleles may be involved in Rad51 overexpression through their deficiency in repairing DNA lesions, which is deleterious for the cell viability and favor selection of cells overexpressing Rad51 to compensate for their own defect. In this one vision, the BCR/ABS gain-of-function and p53, BRCA1 and BRCA2 lss-of-function are causes of Rad51 overexpression. However, a reverse scenario is also possible: Overexpression of Rad51 could be the cause of genetic instability (also deleterious for the cell growth) and then selection of mutations to compensate for it in the genes coding for either p53 or BRCA1 or BRCA2 would occur as a consequence (9). The main support of this hypothesis is that Rad51 overexpression is deleterious in normal cells but it is beneficial for cells with BRCA1 or BRCA2 loss-of-function (10).

The resistance of cancer cells overexpressing Rad51 to DNA damaging agents (MMS, camptothecin, cisplatin) is of utmost interest for cancer chemotherapy (11), but it is questionable whether this is due to overexpression itself or to the accompanying mutations.

We assumed that the use of simple eukaryotic organisms such as yeasts could shed some light on the problem of Rad51 overexpression. It would permit a better differentiation between causes and consequences of this Rad51 status. Rad51 can be overexpressed by putting its gene under the control of an artificial active promoter and testing of the genomic modified strain for resistance/sensitivity to DNA-damaging agents can be performed. In this way, the overexpression being unaccompanied by other mutations, its sole influence on the resistance/sensitivity can be assessed. We carried out the genomic modification and studied its effects in the yeast *Schizosaccharomyces pombe*.

A previous study (12) has shown that overexpression of Rad51/Rhp51 in *Schizosaccharomyces pombe* had deleterious effects on the strain which carried it. Cells had reduced viability and a defect in chromosome segregation at mitosis due to disruption of microtubule attachment to the chromosomes. In this study we confirm loose of viability (to a lesser degree than reported previously (12) and we also report an increased sensitivity to camptothecin and hydroxyurea of transformed cells. However, in strains lacking the *fbh1* gene

(coding for a helicase/translocase which opposes the nucleofilament formation) (13) overexpression of Rad51 conferred lesser sensitivity compared to the strains with normal activity of Fbh1.

MATERIAL AND METHODS

The *S. pombe* strains used in this study, their complete genotype, and their source are presented in tab 1.

Strains AMC 504, AMC60 and 272 were kind gifts from A.M. Carr, University of Sussex UK. The other strains were constructed by us as follows: The *S. pombe* active promoter *nmt1* was inserted upstream of rad51 as described (14, 15). The strain carrying *E-rad22* was obtained similarly but accidental mispriming resulted in a hypomorphic allele (with partial loss-of-function) of rad22. The other strains were derived by standard crosses of 251 (nmt1-rad51) with 272 (fbh1-d) and 266 (E-rad22), followed by sporulation and dissection of the tetrads to obtain spore-clones. They were tested phenotypically (resistance to geneticin meant deletion of fbh1) and genotypically (PCR amplification with a pair of primers, one of them being identical with a sequence in *nmt1* meant overexpression of *rad51*).

TABLE I

***Schizosaccharomyces pombe* strains used in this study**

Culture medium and chemicals: The standard yeast extract agar (YEA) medium was used in all tests (yeast extract 0.5%, glucose 1%) to which camptothecin (Cpt) (Sigma-Aldrich USA) or hydroxyurea (HU, Sigma-Aldrich USA) were added where indicated and in the concentrations shown in figs 1 and 2. The kanamycin-like antibiotic G418 (geneticin Sigma-Aldrich USA) was added at the concentration of 400 mg/l to identify *kanr* (gene which replaces *fbh1* or *rad51*).

Testing of genotoxin sensitivity/resistance: The semi-quantitative "spot test"

was used (13).

RESULTS

Overexpression of *rad51* sensitizes cells to hydroxyurea and camptothecin. Insertion of a variant of the *nmt1* promoter is a frequently used method for overexpressing genes in *Schizosaccharomyces pombe* (14, 16).We first tested the strain with *rad51* placed under the control of the hyperactive promoter *nmt1* for its phenotype. The viability of untreated cells, estimated by the percentage of dead (magdala red dye accumulating) cells in YEA was slightly lower than of the wild-type (WT) cells (not shown).This was not so significant as to be apparent on spot tests (fig. 1, no genotoxin) as reported previously (12). This is probably due to the fact that in our strain there was a single gene under the *nmt1* control (as *nmt1* was inserted upstream of the single chromosomal gene) while Kim et al (12) constructed overexpressing strains using many copies of a plasmid carrying *rad51/rhp51* under the control of *nmt1* promoter. The sensitivity of our strain overexpressing *rad51* to hydroxyurea and camptothecin was higher compared to WT and even higher than sensitivity of the strain deleted of *rad51* (fig. 1 A).

This is not different from other types of wild-type cells, including human cells and even some cancer cells (3) which are also more sensitive when Rad51 is overexpressed. Some types of cancer cells however, especially the ones carrying mutations in BRCA2 (10) are less sensitive to DNA-damaging chemotherapeutics when Rad51 is overexpressed. We tried to reproduce the situation in *S. pombe* by combining the partial loss-of-function of Rad22 (the functional equivalent of BRCA2) (17) with Rad51 overexpression.

The double mutant E-rad22 nmt1-rad51 was not less sensitive than the single-mutant E-rad22. Rad51overexpression did not compensate for the Rad22 deficiency; in that regard the situation described in cancer cells could not be reproduced in *Schizosaccharomyces pombe*. (fig. 1B)

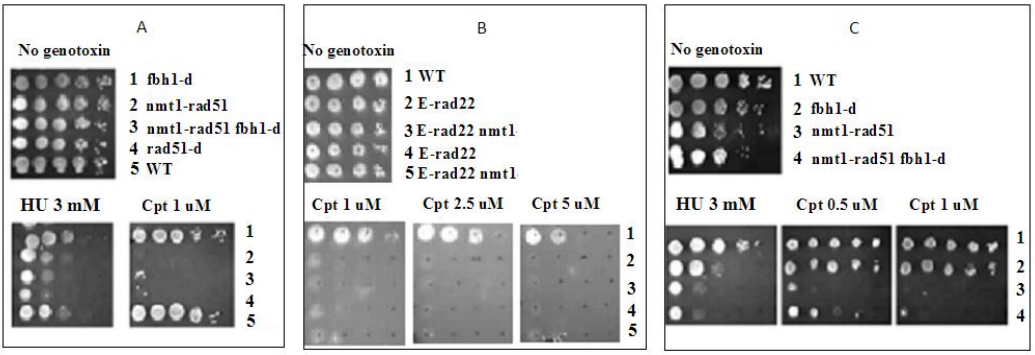

Fig. 1, A, B, C. Viability of *S. pombe* strains with and without mutations at *rad51*, *rad22*, or *fbh1* loci.

Cells were grown to stationary phase and then serially diluted to have 10^5, 10^4, 10^3, 10^2 or 10 cells/5 µl and then 5 µl of each dilution, in the decreasing order from

left to right, was dropped in a row on plates containing the solid medium YEA with or without the genotoxins in concentrations as mentioned . The plates were photographed after 5 days of incubation at 30°C. Panel A: Strains overexpressing Rad51 are hypersensitive to hydroxyurea and camptothecin. Panel B: The Rad22/Rad52 loss-of-function cannot be compensated by overexpression of Rad51. The strains 2 and 4 (317 and 266) were identically mutated at rad22 but they were derived independently and had slightly different genetic backgrounds. The same observation is available for strains 3 and 5 (double mutant's numbers 318 and 319). (tab. I) Panel C: Deletion of the gene *fbh1* alleviates the hypersensitivity to camptothecin of the strain overexpressing Rad51.

Deletion of *Fbh1* gene alleviates the hypersensitivity to camptothecin of strains overexpressing Rad51.

One question that could be raised in respect to the phenotype of Rad51 overexpression is whether it is due to the well known function of the protein in forming the nucleofilament necessary for recombination repair (1) or to a different unknown function. To answer this question we combined overexpression of Rad51 with the lack of a helicase/traslocase function that opposes the nucleofilament formation. Of the several helicases involved we chose Fbh1 which has a homologue in human cells (18, 19). We thus combined *nmt1-rad51*construct with the deletion of *fbh1* gene in the same strain.

We expected that if the excessive formation of nucleofilament had been responsible for genotoxin sensitivity it would have worsened the effect of overexpression (for example to result in less viability even in the cells untreated with genotoxins). This expectance was not confirmed. There was little difference (if any) between the viability of single mutant nmt1-rad51 and double mutant nmt1-rad51 fbh1-d in the media without genotoxin or with hydroxyurea. However, in the media containing camptothecin a clear loss of sensitivity could be perceived in the case of the double mutant nmt-rad51 fbh1-d. In other words, some resistance to camptothecin was visible on the background of Fbh1 loss of function. (fig. 1C)

DISCUSSION

We showed that overexpression of Rad51 sensitized *S. pombe* cells to the action of DNA- damaging drugs hydroxyurea and camptothecin. These two drugs damage DNA by different mechanisms but eventually result in double-strand breaks which are lethal if unrepaired. Their repairing depends on Rad51. Therefore, the absence of Rad51 (as in the case of the strain with the deletion of the gene rad51 (fig.1 A) sensitizes cells to HU and Cpt. We showed in this study that also an excess of Rad51 sensitizes cells to hydroxyurea and camptothecin (Panels A and C).

Is the deleterious effect of Rad51 overexpression due to an excessive formation of nucleofilaments ? The double-strand repair by recombination needs Rad51-dependent nucleofilament assembly in one step of the process and its helicase-dependent disassemble in another step. An excess of Rad51 may distort this balance and lead to an inefficient repair. In this case, the lack of helicase function will augment the unbalance and make the process even less efficient. Therefore we eliminated one of helicase functions by deleting the gene *fbh1* encoding the helicase Fbh1 and found that

the deletion did not add up at the sensitivity to genotoxins or worsen the viability of the cells carrying the double mutation *nmt1-rad51 fbh1-d* (figs. 1 A and C), as expected, were the recombination defects the main cause of the sensitivity. We presume that other functions of Rad51 were in cause. A previous report has shown that Rad51 is involved in cell cycling and mitosis (12), possibly by a different mechanism than that of nucleofilament formation.

Deletion of the helicase/translocase-encoded *fbh1* on the background of Rad51 overexpression had an unexpected effect: the diminution of sensitivity to camptothecin. (fig. 1 C). This is a reminiscent of the resistance of cancer cells overexpressing Rad51 to DNA-damaging chemotherapy. In our view, this finding may be interpreted in two alternative ways: 1. Hypersensitivity to camptothecin of the strain overexpressing Rad51 is not due to its effect over the nucleofilament formation and efficiency of recombination but to a different mechanism. Recombination is not affected as long as Fbh1 helicase/ translocase exists. When the helicase function does not exist, repair by recombination is more efficient and this leads to a relative resistance to camptothecin - relative because the main mechanism which is the cause of sensitivity is not suppressed - (the physiologically-based hypothesis). 2. The double genomic modification which confers the Rad51 overexpression on the background of the Fbh1 absence leads to a genomic instability and to a new mutation conferring resistance to camptothecin. The resistant cells select in the medium containing camptothecin (the genomic instability hypothesis). We cannot as yet distinguish between these two hypotheses, but the second one (genetic instability hypothesis) can be checked by genetic methods: selection of the clone presenting stably a less sensitivity to camptothecin, loss and regain of this capacity in crosses and, eventually, identification the mutated gene. That we are going to carry out further.

Relevance of our findings to the problem of cancer cells overexpressing Rad51 and their resistance to chemotherapeutics: We started this study as an attempt to reproduce in fission yeast and explain the resistance to DNA-damaging agents of cells overexpressing Rad51. Our attempt was justified by the fact that the action of DNA-damaging chemotherapeutics, the mechanisms of DNA repair and the proteins involved are similar in human cells and in yeasts. We did not find that fission yeast overexpressing Rad51 was resistant to any of two DNA-damaging agents hydroxyurea and camptothecin either Rad51 overexpression singly or accompanied by the functional equivalent of BRCA2 (Rad52/Rad22) loss-of-function. This is different from cancer cells in which association between Rad51 overexpression and BRCA2 loss-of-function is thought to cause resistance to DNA-damaging agents. However, one of our findings in this work on *S. pombe* points to recombination being involved in resistance. This is the alleviation of sensitivity to camptothecin of fission yeast cells deleted for the gene coding for helicase/translocase Fbh1. Fbh1 protein is also present in mammalian cells (19).

CONCLUSIONS

This work attempted to reproduce in fission yeast the Rad51 overexpression and resistance to DNA-damaging chemotherapeutics described in cancer cells. We found that overexpression of Rad51 in fission yeast sensitized cells to DNA damaging

agents, but sensitization was alleviated by the loss-of-function of the helicase/translocase Fbh1. This draws attention to a protein also present in human (and therefore in cancer) cells that may be involved in resistance either by its role in recombination or as a genetic stabilizer.

ACKNOWLEDGEMENTS. This work has benefitted from the grant 17075/30.09.2010 "Study of physical and functional interactions of Sp-Rad52 protein, involved in DNA double strand repair, using a genetically modified protein" attributed by UMF Iasi. We thank A.M. Carr, Sussex University Brighton UK for yeast strains and plasmids. We used the laboratory facilities of the Platform of Molecular Medicine, University of Medicine and Pharmacy "Grigore T. Popa" Iasi.

NEWS

MULTIFOCAL GENITAL HERPES SIMPLEX VIRUS TYPE 2 INFECTION

Genital HSV reactivation is thought to be anatomically and temporally localized, coincident with limited ganglionic infection. Subclinical shedding episodes are the most common form of HSV-2 reactivation, with host clearance mechanisms leading to rapid containment.To precisely define patterns of anatomic reactivation, Johnston and co. divided the genital tract into a 22-region grid and obtained daily swabs for 20 days from each region in 28 immunocompetent, HSV-2 seropositive persons. HSV was detected via PCR and sites of asymptomatic HSV shedding were biopsied within 24 hours. They quantified CD4+ and CD8+ T cells by immunofluorescence, and HSV specific CD4+ T cells were identified by intracellular cytokine cytometry. HSV was detected in 868 of 11,603 genital swabs at a median of 12 sites per person. Bilateral HSV detection occurred on 83 days with shedding, and the median quantity of virus detected/day was associated with the number of sites positive ($p<0.001$). In biopsies of asymptomatic shedding sites, we found increased numbers of CD8+ T cells compared to control tissue (27 vs. 13 cells/mm^2, $p=0.03$) and identified HSV specific CD4+ T cells. HSV reactivations emanate from widely separated anatomic regions of the genital tract and are associated with a localized cellular infiltrate that was demonstrated to be HSV-specific in 3 cases. The authors concluded that HSV-2 reactivation can be detected at multiple, bilateral sites in the genital tract, suggesting that HSV establishes latency throughout the sacral ganglia. In addition, genital biopsies from sites of asymptomatic HSV shedding have increased numbers of CD8+ T cells compared to control tissue, and HSV-specific CD4+ T cells are found at sites of asymptomatic shedding. These findings suggest that that widespread asymptomatic genital HSV-2 shedding is associated with a targeted host immune response and contributes to chronic inflammation throughout the genital tract. (Johnston C, Zhu J, Jing L, Laing KJ et al. Virologic and immunologic evidence of multifocal genital herpes simplex virus type 2 infection. *J Virol*. 2014 Feb 19. [Epub ahead of print] PMID: 24554666)

ASPECTS REGARDING THE HYGIENIC-SANITARY CONDITIONS AT THE LEVEL OF CERTAIN DENTAL MEDICINE CABINETS IN IASI COUNTY

E.R. Cernei[1], Dana Cristiana Maxim[1], L.L. Indrei[2]
University of Medicine and Pharmacy "Grigore T. Popa"-Iasi
Faculty of Dental Medicine
1. Discipline of Pedodontics
Faculty of Medicine
2. Discipline of Hygiene-Environmental Health

ASPECTS REGARDING THE HYGIENIC-SANITARY CONDITIONS AT THE LEVEL OF CERTAIN DENTAL MEDICINE CABINETS IN IASI COUNTY (Abstract) **Aim**: This baseline study aims to find out the evaluation of hygienic-sanitary conditions at the level of dental medicine cabinets through the verification of certain hygienic aspects. **Material and Methods:** The study conducted consists in monitoring the hygienic/sanitary conditions at the level of 68 dental medicine cabinets (40 private cabinets and 28 school/university dental cabinets in Iasi county), using sheets for the assessment of the hygienic/sanitary conditions adapted from the control sheets of existing dental medicine cabinets at the level of DSP (Public Health Department) Iasi. **Results and discussion:** The sheets for the assessment of the hygienic/sanitary conditions were evaluated by a specialized team and the results were illustrated in the specific charts. At the level of all the dental cabinets the study revealed non-conformities regarding the means to carry out cleaning, disinfection operations, including the management of perilous waste, the control of medical personnel. **Conclusions:** An optimization of the hygienic-sanitary conditions at the level of dental medicine cabinets is still necessary, through participation to the activity of personnel training**,** who is directly involved in dental medical assistance. **Keywords**: HYGIENIC-SANITARY CONDITIONS, DENTAL MEDICINE CABINETS, ASSESSMENT

The evaluation of hygienic-sanitary conditions at the level of dental medicine cabinets through the verification of certain hygienic aspects, as well as of the environment's parameters, with the identification of deficiencies and the implementation of some measures to fix them is an objective of priority in view of ensuring a quality dental assistance by means of removing bacterial, viral and mycotic infections as well as by assessing the epidemiologic risk (1, 2, 3).

MATERIAL AND METHODS

The study conducted consists in monitoring the hygienic/sanitary conditions at the level of 68 dental medicine cabinets (40 private cabinets, 20 from the urban environment and 10 from the rural environment) and 28 school/university dental cabinets in Iasi county, using sheets for the assessment of the hygienic/sanitary conditions adapted from the control sheets of existing dental medicine cabinets at the level of DSP (Public Health Department) Iasi (4, 5, 6, 7).

The following aspects were monitored:

- Functional structure of cabinets;
- Their location;

- Access;
- Existence of functional circuits and compliance with them;
- Washable surfaces;
- Supply with drinkable water;
- Existence of sinks for cleaning instruments and for the hygiene of hands;
- Connection to the sewage system;
- Natural and artificial lighting;
- Status of sanitary groups;
- Thermal microclimate;
- Manner of sanitary materials' sterilization;
- Compliance with norms regarding the handling operations of used instruments;
- Existence of cleaning materials;
- Existence of disinfectant and antiseptic substances approved by the MS (Ministry of Health);
- The way decontaminants are used and their existence in stock;
- The situation of medical and auxiliary personnel;
- The management of dangerous waste according to Order 219/2002;
- Cabinets' facilities.

RESULTS AND DISCUSSION

Out of the 68 dental cabinets under investigation, a number of 40 are private, the rest being school/university dental cabinets (fig. 1).

Out of the 40 cabinets of private dental medicine, 30 (75%) are from the urban environment, while 10 (25%) from the rural one (fig. 2).

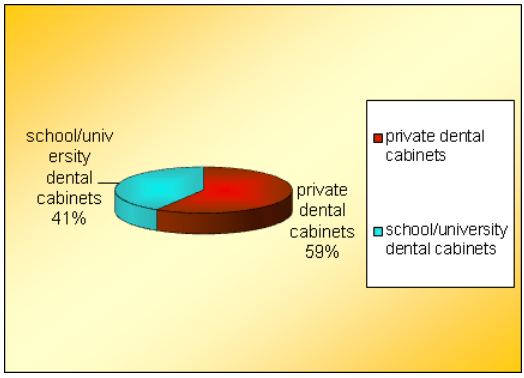

Fig. 1. Repartition or distribution of dental cabinets – depending on the form of organization.

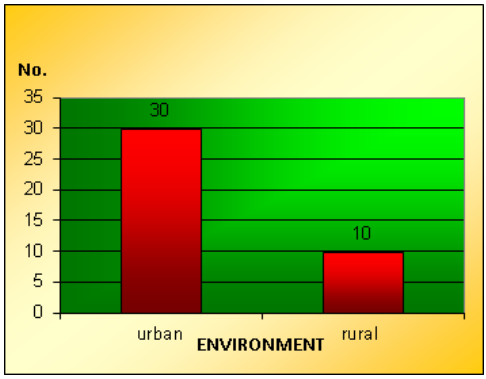

Fig. 2. Repartition or distribution of dental cabinets – depending on the environment

The number of rooms varies between 6 and 8 rooms, including the dental cabinet as such, an office, a sterilization room, dressing room, waiting room, temporary storage room for dangerous waste, 1-2 washrooms. The surface of the dental cabinet itself varies from 12 to 22 square meters.

At a number of 49 cabinets there is no sterilization room, the sterilization being conducted at the level of the cabinet itself.

Out of the 68 dental cabinets**,** 19 operated at the ground floor of blocks of flats, 5 in houses, 16 with commercial venues whose construction was destined to medical activities and the 28 school/university den-

tal cabinets operated inside the academic buildings (fig. 3).

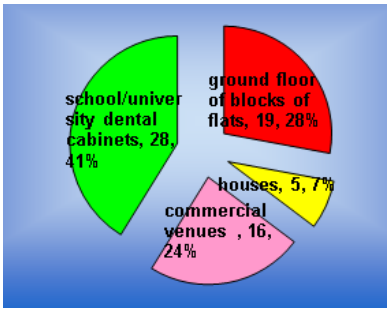

Fig. 3. Repartition or distribution of dental cabinets – depending on the location

Access to the dental practice was identified as follows:

- Separated from that of inhabitants at a number of 60 cabinets (28 school/university cabinets and 32 private dental cabinets);
- Common with that of the inhabitants at 8 private dental cabinets (blocks of flats, living houses) (fig. 4).

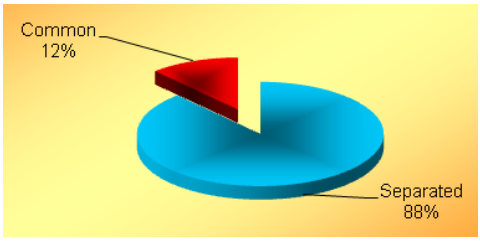

Fig. 4. Repartition or distribution of dental cabinets – depending on the access

The dental cabinets under investigation had proper functional circuits, but at a number of 10 private dental cabinets these circuits were not observed, the functional circuits being modified due to the installation of new equipment in those particular cabinets.

All cabinets under investigation had washable surfaces (floors), with differences related only to the materials used:

Out of the 28 school/university cabinets under investigation, 21 (75%) had mosaic floor and 7 (25%) floor tiles.

At the private dental cabinets under investigation a number of 13 cabinets had mosaic floor, 20 floor tiles and 7 heavy duty traffic linoleum (*tarkett*) and epoxy resin.

In rural environment there are mostly mosaic surfaces (dental cabinets in old buildings) – 7 cabinets, only 3 cabinets having tile floors (fig. 5).

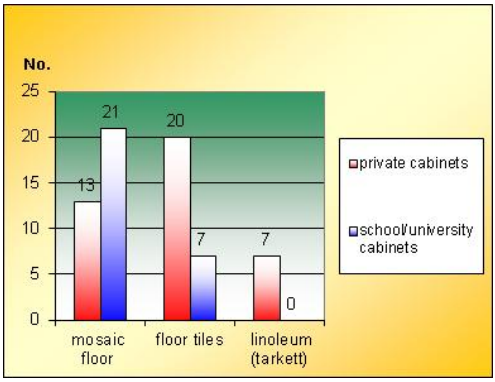

Fig. 5. Repartition or distribution of dental cabinets – depending on the surface/form of organization

The 58 dental cabinets in the urban environment (28 school/university and 30 private) are connected to the central distribution network of **potable water**, cold water being delivered on a permanent basis.

In the rural environment, out of the 10 cabinets under investigation, 5 were connected to the central water network while for the other 5 cabinets potable water supply was ensured through individual installations.

A cabinet in the rural environment connected to the centralized network had no

current water at the moment of the investigation due to some construction works, the cabinet having no supplies of potable water at the moment of the control (fig. 6).

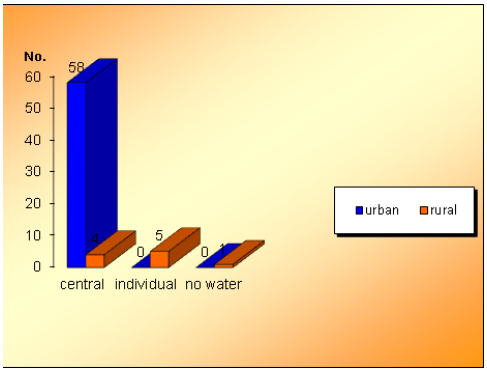

Fig. 6. Repartition of dental cabinets – depending on the potable water supply

All dental cabinets investigated has a **supply of hot water,** its existence being an essential condition for compliance with the hygienic-sanitary conditions at the level of the cabinets in view of a good performance of their activity.

Thus, out of the 40 private cabinets, 19 cabinets were connected to the city's centralized network of hot water and 21 had individual installations (thermal units and electric boilers).

Out of the 28 school/university dental cabinets, 15 were connected to the centralized network of hot water while for the rest hot water was supplied through individual installations (thermal units, electric boilers, instant boilers) (fig. 7).

In the rural environment, the 10 cabinets had mostly own installations (electric boilers, thermal units).

In all 68 dental cabinets under investigation there are sinks with separate destination: for handling the instruments and for the hygiene of the personnel's hands.

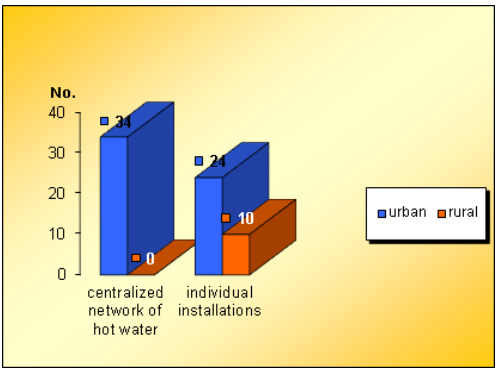

Fig. 7. Repartition of dental cabinets – depending on the means of producing hot water

There is a connection to the city's sewage system in view of evacuating **residual waste** for all cabinets (school/university and private cabinets) in the urban environment. The evacuation of residual waste for the 10 cabinets in the rural environment is conducted by means of septic tanks.

The existence of **washrooms for the medical staff separate from the patients' occurs** mainly in the case of dental cabinets destined by construction to medical activities and in the case of school/ university dental cabinets, where there are several sanitary groups.

In case of 18 private cabinets in the urban environment there is no possibility to build a second sanitary unit as the cabinets have been transformed from apartments to medical cabinets.

In the rural environment, 5 private cabinets have two sanitary groups, namely for the medical staff and for the patients.

A **natural and artificial** lighting is ensured in all dental cabinets in optimum conditions.

The thermal microclimate at the level of the 68 cabinets is ensured as follows: 19 dental cabinets were connected to the city's

heating network, 21 had individual installations (thermal units, stoves in the rural environment), while out of the 28 school/university dental cabinets 15 were connected to the centralized heating network and the rest of 13 had individual installations (thermal units) (fig. 8).

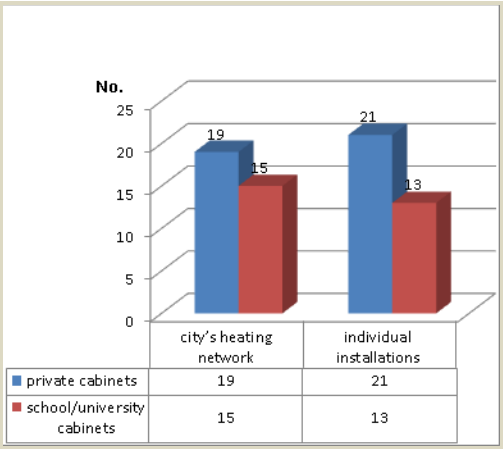

Fig. 8 Repartition of dental cabinets – depending on the means of accomplishing the thermal climate

A number of 42 dental cabinets investigated (35 of the private cabinets and 5 of the school/university cabinets, as well as 2 out of the rural environment) were endowed with **air-conditioning systems** in view of ensuring thermal comfort for the hot season.

With regard to the **sterilization of sanitary materials,** from the 68 cabinets investigated, for a number of 19 cabinets sterilization was carried out in a specially designed space – the sterilization room, while for the rest sterilization was carried out at the level of the cabinet itself. In all cases, the sterile material was not mixed up with the non-sterile one, there being no contamination danger.

All cabinets had hot air sterilizing units (*Poupinel* type), but only 16 had sterilizing units with vapors under pressure (autoclave). In all cases, the equipment used in view of sterilizing instruments and soft materials were authorized and approved by the regulating agencies.

For a number of 30 dental cabinets under investigation, there was no **technical control** conducted for the sterilizing units by specialized companies.

With regard to the correct **tallying of the sterilization procedures** as well as the **use of self-control tests**, for a number of 10 dental cabinets there were found deficiencies concerning: the proper filing of procedures by failure to cover all boxes of the Sterilization Record Book, knowledge of the sterilization technique, proper marking of self-control test kits, insufficient supplies as well as invalid expiry date for the tests – a deficiency found at one dental cabinet.

At a number of 5 cabinets, there were found deficiencies regarding the **storage and labeling** of the sterilized kits.

Handling instruments in view of sterilization is carried out properly at the 40 private cabinets, except for the 28 school/ university cabinets, which use the same solution (detergent/disinfectant) for the two stages of handling the instruments, there being no disinfectant for stage 2.

With regard to the **cleaning and disinfection materials** used at the level of the cabinets, there are sufficient quantities in stock for a number of 50 cabinets, while for the rest of the cabinets (18 school/ university cabinets) there was an absence of a proper supply of detergent-disinfectant, as well as of cleaning materials. At 8 dental cabinets (private and school/university) there was an improper storage of cleaning and disinfection materials.

The use of **decontaminants** is conducted with the observance of the instructions of use, at the concentrations at times specified by the producer at a number of 55 dental cabinets out of the 68 cabinets investigated, while at a number of 10 school/university cabinets and 3 private cabinets the decontaminants were used improperly.

The number of doctors who perform their activity at the level of dental cabinets varies from 1 to 6, depending on the dental units inside the cabinets.

A peculiar situation is the present of **auxiliary sanitary personnel (nurses)**; out of the 40 private dental cabinets, 29 were operating without a nurse and at the level school dental cabinets 5 were operating without nurses.

With regard to the personnel's **medical exams,** we found out that the provisions of the Emergency Ordinance 355/2007 regarding the surveillance of the health condition of the personnel were not complied with entirely, out of the 68 dental cabinets 10 failed to show medical exams according to the technical norms of Ministry of Health (8).

As a rule, the **protection equipment** is used in all cabinets but most of the times it is incomplete (absence of goggles and mask). The single-use gloves are used by doctors in 90% of the cases in the cabinets under investigation. The medical personnel were found to be vaccinated for B hepatitis.

Another problem encountered at the level of school/university cabinets is the **high number of pupils/students** per doctor, dental assistance being granted by a single doctor to a large number of students.

A special issue which arises in dental practice is related to the **management of solid waste,** in agreement with the Order of the Minister of Health no. 219/2002, especially of perilous waste resulted from the medical practice (9,10).

At the level of the 28 school/university dental cabinets and at a number of 30 private cabinets, there are no **temporary storage facilities for perilous waste** functionally separate from the rest of the construction, in the rest of the cases there being spaces inside constructions.

Primary recollection of waste with septic potential is carried out separately from sewage waste in all cases, but at a number of 10 private dental cabinets and at a number of 11 school/university cabinets the cutting/piercing waste was collected in carton boxes indiscriminately with septic waste.

The recipients - the bags used – are identified differently (yellow with the icon "Biologic Hazard" for perilous waste and black for domestic garbage). At a number of 10 cabinets it was assessed that the bins were not washed and disinfected every time they were emptied.

All private dental cabinets investigates **have entered contracts with a specialized authorized company for the transportation and elimination** of hazardous waste. The contract wasn't renewed in the case of 5 school/university dental cabinets.

At a number of 10 school/university dental cabinets, as well as at the level of the dental cabinets in the rural environment the **schedule for the collection of perilous waste** is not observed, the collection being carried out every two-three days or even more, in breach of the provisions of the Order of the Minister of Health no. 219/2002, due to the fact that contracts for school/university dental cabinets were not renewed and, for the rural environment, the motivation of companies being that, given

the small operational volume of medical waste the collection is not economically justified.

With regard to the cabinet facilities, it was assessed that there is proper **furniture, instruments and medical equipment** at the level of the private dental cabinets while for the 28 school/university dental cabinets a number of 5 had improper worn-out furniture, instruments and equipment.

CONCLUSIONS

At the level of school/university dental cabinets the study assessed deficiencies regarding:

- The supply with cleaning and disinfectant substances, as well as in their proper use;
- The use of the same solution (detergent- disinfectant) for the two stages of instrument handling, stage two disinfectant being absent;
- Management of perilous waste (improper collection, the waste being stored at the level of the cabinet for long intervals, sometimes for weeks, due to insufficient funds which prevent the conclusion of a contract with a specialized waste management company;
- The absence of temporary storage locations of perilous waste;
- Endowment with proper furniture, instruments and medical equipment;
- Absence of auxiliary sanitary personnel there being cabinets functioning without a medical nurse;
- The existence of a large number of patients (pupils/students) for a single doctor;
- The personnel's periodic medical exams and the proper use of the protection equipment.

At the level of private dental cabinets the study revealed nonconformities regarding:

- Compliance with functional circuits due to the installation of new equipment;
- Non-familiarization with the proper way to handle instruments in view of sterilization;
- Deficiencies regarding the sterilization process (non-familiarization with the sterilization technique, proper recording of sterilization, non-marking of self-control kits, failure to conduct a technical control of the sterilization equipment);
- Deficiencies regarding the storage and collection of perilous waste resulted from the medical activity (failure to observe the schedule of waste collection by the authorized companies, especially in the rural environment);
- The study assessed no deficiencies regarding the supply with cleaning and disinfectant substances as well as their proper use.

GINGIVAL EVALUATION IN CHILDREN WITH CONGENITAL CARDIOVASCULAR DISEASES

Children with congenital cardiovascular diseases who suffer from dental diseases present an increased risk of infective endocarditis. Oral inflammatory diseases may also increase the severity of their cardiovascular condition. The purpose of a study realized by a group of american researchers was to evaluate the gingival status of children with congenital cardiovascular diseases in comparison to healthy children. In the study were included 50 children, aged between 7 and 13 year old. The test group comprised 25 children with congenital cardiovascular diseases subdivided into 3 groups: *the first group*- unrepaired ventricular septal defect; *the second group* - aortic valve stenosis; *the third group* - coarctation of the aorta. The control group consisted of 25 healthy age- and gender-matched children. Plaque, calculus, gingivitis and recession were measured on 12 teeth, six sites per tooth. The results showed that children with congenital cardiovascular diseases had significantly more plaque (P<.001), calculus (P<.001), gingivitis (P<.001) and recession (P>.02) than control group. Among the congenital cardiovascular diseases groups, no statistically significant differences were found for plaque, gingivitis or recession. The conclusions of the study showed that children with congenital cardiovascular diseases had a higher prevalence of periodontal disease, evidenced by gingivitis, plaque, calculus, and recession. These children should be evaluated periodontally and their oral health monitored on a 3-month basis to prevent disease development, benefit cardiovascular condition, prevent endocarditis and to improve quality and longevity of life. METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* CARRIAGE IN INFANTS WITH PROTEIN-ENERGY MALNUTRITION

Laura Florescu[1], Teodora Vremeră[2], Genoveva Bălănică[1], Mioara Calipsona Matei[3], Luminița Smaranda Iancu[2]

3. Discipline of Primary Health Care and Epidemiology

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* CARRIAGE IN INFANTS WITH PROTEIN-ENERGY MALNUTRITION (Abstract) **Aim:** The aim of the present study was to investigate the frequency of methicillin-resistant *S. aureus* (MRSA) colonization in infants with protein-energy malnutrition (PEM) and to characterize the antibiotic susceptibility patterns in isolated strains. **Material and methods:** The study included 123 infants with PEM, admitted to the Paediatric Rehabilitation Department of „St. Mary" Emergency Clinical Children's Hospital Iaşi, during October 1st 2010 and August 30th 2011. Nasal, pharyngeal and conjunctival swabs were collected for detection of colonization upon admission and at discharge. **Results:** The study revealed a high rate of MRSA carriage among infants with PEM (62.60%), most of the isolated strains being multidrug-resistant (86.13%), with additional resistance to aminoglycosides, macrolides and inducible resistance to clindamycin. 88% of colonized infants were nasal carriers. **Conclusions:** Identification of MRSA carriers permits the implementation of measures that decrease the risk for subsequent infection. **Keywords**: *STAPHYLOCOCCUS AUREUS*, MRSA, PEM.

Staphylococcus aureus can cause a wide range of diseases, from local to deep-seated infections, in all age groups, in both hospitals and community worldwide (1). The emergence and spread of multi-drug resistant (MDR) methicillin-resistant *S. aureus* (MRSA) strains have raised the problem of finding efficient treatment of staphylococcal infections. *S. aureus* is part of the normal flora in a significant fraction of the healthy population. However, persistent carriers are known to have a higher risk of developing *S. aureus* infections (2). Nasal colonization with MRSA strains is increased in settings where people are in close contact and neonates and infants are particularly more susceptible to colonization and infection with MRSA, one of the most versatile of childhood pathogens (1, 3, 4). This risk is increased in infants with protein-energy malnutrition (PEM), a potentially fatal nutritional disorder, encountered in children world-wide and often associated with a wide variety of infections (5).

The objectives of this study were to investigate the frequency of MRSA colonization in infants with PEM, to characterize the antibiotic susceptibility patterns in

isolated strains, as well as to evaluate the performance of surveillance through cultures at various body sites for *S. aureus* colonization.

MATERIAL AND METHODS

The study included 123 infants with PEM, aged between 5 and 48 weeks, admitted to the Paediatric Rehabilitation Department of „St. Mary" Emergency Clinical Children's Hospital Iaşi, during October 1st 2010 and August 30th 2011. Of the infants included in the study, 107 were born in maternity (87%), 46 required resuscitation manoeuvres (37, 4%), and 53 received complex treatment in Neonatal Intensive Care Unit (43,1%). Nasal, pharyngeal and conjunctival swabs were collected upon admission and at discharge. The samples were subsequently processed at "Grigore T. Popa" University of Medicine and Pharmacy Iaşi, Microbiology Department.

The complete antimicrobial susceptibility patterns were evaluated using disk diffusion method, as recommended by Clinical and Laboratory Standards Institute (CLSI) guidelines 2010. We tested the sensitivity to the following antibiotics: penicillin (P), oxacillin (OX), cephoxitin (FOX), clindamycin (CM), erythromycin (E), tetracycline (TE), gentamicin (G), tobramycin (T), kanamycin (K), rifampicin (RIF), trimethoprim / sulfamethoxazole (SXT), fluoroquinolones (FQ), linezolid (LZD) and teicoplanin (TEC). Inducible resistance to CM (iCM) was assessed by double-disk (E and CM) diffusion method (D-zone test). Minimum inhibitory concentrations (MICs) for vancomycin (VA) and OX were determined using E-test method (*bioMérieux*, France). Multi-drug resistance among MRSA was defined as concurrent resistance to three or more non-beta-lactam antimicrobial agents.

RESULTS

A total of 114 *S. aureus* strains were isolated from 84 patients (68.29% of the total number of infants) upon admission (52 strains) and at discharge (62 strains), as follows: in 30 infants *S. aureus* was found both upon admission and at discharge, 22 infants carried *S. aureus* only upon admission and in 32 infants *S. aureus* was found only at discharge. In 42 patients *S. aureus* was found only in nasal swabs, in 32 cases nasal and extra nasal carriage was detected, while 10 infants were colonized only extranasally.

Of the total number of *S. aureus* strains, 101 were MRSA (88.59%), isolated upon admission (43 strains), as well as at discharge (58 strains) from 77 infants (62.6% of the total number of infants and 91.66% of colonized infants). Most MRSA strains were isolated from nasal swabs (66.33%).

The sensitivity of 30 µg cephoxitin disk testing was 99% when compared to MIC detection. MICs for OX varied between 0.125-256 µg/ml, with a heteroresistance rate of 14.85 % of the total number of strains. A high proportion of strains (42.98%) showed OX MICs of > 256 µg/mL. MICs for VA were in the susceptible range, varrying from 0.125 to 2µg/mL. MIC_{50} and MIC_{90} values were as follows: for OX – 64 µg/Ml, and > 256 µg/mL respectively, and for VA – 1 µg/mL, and 1.5µg/mL respectively.

Of 101 MRSA strains, 87 were MDR (86.13%). MRSA isolates had additional resistance to aminoglycosides (fenotype KTG – 60 strains and fenotype K – 37 strains), macrolides (93 strains), tetracyclines (82 strains) and iCM (87 strains). Twelve different antibiotic resistance patterns were observed among MRSA isolates,

the most frequent profile being: resistant to KTG, E, iCM, TE and intermediate to DO (32 strains), found upon admission (15/32) as well at discharge (17/32). Among the resistance patterns studied, we noticed the predominance at admission of the profile resistant to K, E, iCM, TE, intermediate to DO (10/17), and the predominance at discharge of isolates belonging to the profile resistant to KTG, E, iCM, TE (11/15)

Methicillin susceptible *S. aureus* (MSSA) showed increased susceptibility to antibiotics compared to MRSA strains, the majority being resistant only to P (9/13), while two of them were also resistant to aminoglycosides and other two were resistant to tetracyclines. Most MSSA strains were detected upon admission (9/13).

All strains were sensitive to LZD, VA, TEC, SXT, FQ, and RIF. There was no case of associated or subsequent staphylococcal infection in colonized infants.

DISCUSSION

In our country, the number of infants with PEM remains high due to certain specific situations: tendency to stop breastfeeding precociously, gradually intensified during the last decades; inability to ensure a proper artificial nutrition during the first months of life mainly due to lower revenue; a great number of children from disorganized families or abandoned at birth (6). Their nutritional recovery is a long process which requires continuous medical surveillance in care units and, on the other hand, long-term hospitalization predisposes to infection.

S. aureus is an important nosocomial pathogen (7). Colonization with *S. aureus* has been described as a risk factor for infection (8) and seems to be associated with an increased risk of atopic dermatitis in infants, although the latter is still disputed. A study by Lebon *et al.* showed that *S. aureus* colonization at 6 months and frequent colonization in the first year of life are associated with moderate to severe atopic dermatitis, while in a study by Skov *et al.*, no such relation was found (2, 9).

Colonization with MRSA strains poses a greater risk of infection than MSSA colonization and usually precedes invasive infection (7, 8). A study by Davis *et al.* shows that 19% of patients colonized with MRSA at admission and 25% of those colonized during hospitalization developed infection, compared with 1.5% of patients colonized with MSSA and 2.0% of patients uncolonized. MRSA carriage at admission was found to increase the risk of infection, compared with MSSA carriage or no staphylococcal colonization at admission (7). However, according to Fritz *et al.*, MRSA nasal carriage is mostly self-limited, compared to MSSA carriage which seems to be more persistent (10). The anterior nares are the most frequent carriage site (2). It is estimated that 20–40% of healthy individuals are nasal carriers (1). We have evaluated 3 sites for *S. aureus* colonization: nares, oropharynx and conjunctiva. We found that nasal cultures were able to detect carriage in 88% of colonized infants, the rest of the patients being colonized only extranasally. A study by Cursino *et al.* evaluated 4 sites for colonization in newborns from Brazil and concluded that multiple culture sites are needed, a combination of nares and umbilical samples detecting 86% of MSSA and 91% of MRSA colonization cases (11).

The rate of staphylococcal colonization among normal weight children varies greatly with age, being 40 - 50% in newborns

and infants during the first 8 weeks and falls to 21% by 6 months (11,12, 13) According to Chatzakis *et al.*, the rate of infant carriage in Greece was lower, 17.7% respectively (14). In a study by Sedighi *et al.*, in Iran, 22.5% of children from day-care centres were carriers, but the rate of MRSA colonization was very low (4.1%) (3). In Romania, a study by Constantiniu *et al.* revealed a rate of *S. aureus* colonization among children in community of 7.18%, of which only 5.4 % were MRSA (15). Among our patients, the rate of colonization with *S. aureus* was very high (68.29%), of which the majority were colonized with MRSA (91.66%).

Persistent colonization poses a higher risk of staphylococcal infections. Children are thought to have higher persistent carriage rates than adults (13), although Lebon *et al*. dispute that in infant population those carriers are rare (2). Children with persistent staphylococcal colonization often carry identical strains (10). Our study revealed that 8.33% of colonized infants carried *S. aureus* strains with identical antibiotic resistance patterns upon admission and at discharge, while 27.38% had strains with different resistance profiles which suggest that, in some cases, the source of these strains was the care unit. On the other hand, no case of subsequent infection occurred among infants colonized at admission to the hospital or in those who developed colonization during hospitalization. We note that persistent carriage needs to be evaluated periodically during hospitalization and even after discharge, since, in many cases, transition to intermittent or noncarriage state is possible. The isolation of *S. aureus* strains in a high percentage of infants after admission to hospital could be explained by the high rate of pathological antecedents together with the immune deficit due to malnutrition, but it could also be caused by close contact during hospitalization or transmission from colonized mothers. In a study by Peacock *et al*. (UK) the source for infant colonization was usually represented by the mother (12). In our study, staphylococcal colonization in mothers was not investigated.

We appreciate that the increase in MRSA colonization was facilitated by the long hospitalization duration which was needed to improve weight deficit and the acquired immunodeficiency by low nutrient intake.

Infants that were healthy carriers did not receive topical mupirocin ointment because it was not available for purchase.

We emphasize that the sanitary rules have been respected, and we tried to ensure optimal conditions for nursing, in order to limit the involvement of environmental factors in the dissemination of S. *aureus*. However, we have not managed to maintain, throughout the duration of the study, an effective ratio of staff to children, because of an acute shortage of medical staff.

CONCLUSIONS

We conclude that colonization by *S. aureus* and MRSA strains is common in infants with PEM hospitalized in Paediatric Rehabilitation Department (68.29% and 62.6%, respectively), much higher compared with studies from other countries, with the major remark that citated studies were about children with normal weight; no subsequent staphylococcal infections were reported. Antimicrobial susceptibility testing revealed a worryingly high rate of multidrug-resistance among MRSA strains

isolated from colonized infants (86.13%).

Given the age group studied and the antibiotic sensitivity spectrum of MRSA strains isolated, we consider linezolid and vancomycin as therapeutic options in the case of colonized infants that develop subsequent staphylococcal infection; cotrimoxazole can be used in infants older than 2 months, and fluoroquinolones are not recommended because of their adverse effects.

This study highlights the need to improve primary care to ensure an adequate nutritional status of infants, in order to disrupt the vicious circle malnutrition - infection - malnutrition.

Detecting MRSA colonization at admission allows us to identify a high-risk population and facilitates the implementation of strategies for decolonization and reduction of MRSA transmission and infections.

NEWS

CARDIOVASCULAR EFFECTS OF INTENSIVE LIFESTYLE MANAGEMENT IN PATIENTS WITH TYPE 2 DIABETES

Weight loss and healthy eating are recommended for overweight and obese patients with type 2 diabetes due to the positive effects verified in the short term but long-term cardiovascular effects have not been demonstrated. In 16 U.S.A. centers were randomized 5145 patients with type 2 diabetes, overweight and obese, who received a hypo caloric diet and exercise training (intervention group) versus medical treatment of diabetes (control group). The main objective was to quantify the deaths from cardiovascular causes, cerebral, myocardial infarction, and hospitalization for angina, for a follow-up of 13.5 years. The trial was stopped early, after a period of 9.6 years, as it was reported that, although it was a significant decrease in weight (8.6% *vs.* 0.7% at one year, 6% vs. 3.5% at the final), the difference in cardiovascular morbidity and mortality was only 403 patients in the intervention group compared to 418 in the control group (p = 0,51). The remaining benefits were significant lifestyle changes: decreased glycosylated hemoglobin, partial remission of diabetes, reduction of urinary incontinence, sleep apnea, depression and quality of life. (The Look AHEAD Research Group, Cardiovascular effects of intensive lifestyle intervention in type 2 diabetes, *N Engl J Med* 2013; 369: 145-154)

NATURAL CONCEPTION FOLLOWING TOTAL FERTILIZATION FAILURE WITH INTRACYTOPLASMIC SPERM INJECTION IN A COUPLE WITH UNEXPLAINED INFERTILITY: A CASE REPORT (Abstract): With the introduction of intracytoplasmic sperm injection (ICSI), couples with severe male factor infertility have been able to achieve fertilization and clinical pregnancy rates comparable to other in vitro fertilization patients. However, despite the utilization of microsurgical sperm injection techniques, failure of fertilization still occurs in a few patients. How such fertilization failure after ICSI might impact later ICSI treatments is less understood. We report a case of total fertilization failure after ICSI using sperm from a normozoospermic husband of a patient with unexplained infertility. Six months after the cancelled cycle, the couple conceived naturally. Unfortunately, it was an ectopic pregnancy, which required laparoscopy and surgical removal of the right fallopian tube. This case shows that a failed ICSI cycle, therefore, does not imply a hopeless prognosis for future ICSI treatment. Moreover, in cases with unexplained ICSI failure, natural conception can subsequently occur. The aim of this study is two-fold: to discuss a rare case of a spontaneous pregnancy after total fertilization failure with ICSI and to develop counseling material for patients and doctors who are faced with such a rare situation. To our knowledge, this is the first report of a case of spontaneous pregnancy after total fertilization failure with ICSI. **Keywords:** TOTAL FERTILIZATION FAILURE, INTRACYTOPLASMIC SPERM INJECTION, UNEXPLAINED INFERTILITY.

Intracytoplasmic sperm injection (ICSI) is a method of micromanipulation used to deposit a spermatozoon directly into the oocyte cytoplasm. When all other forms of assisted fertilization are unsuccessful, ICSI is the method of choice to overcome male infertility. ICSI has enabled fertilization of oocytes from patients whose partners have extremely low numbers of viable sperm and a very low probability of achieving fertilization after conventional spermoocyte incubation in vitro. ICSI is possible with spermatozoa obtained from ejaculate, percutaneous epididymal sperm aspiration (PESA), microsurgical epididymal sperm extraction (MESE), or testicular sperm extraction. In addition, indications for ICSI include unexplained infertility and previous conventional in vitro fertilization (IVF) failure. Although the fertilization rates

after ICSI are relatively high (1), some injected oocytes fail to fertilize despite the presence of a spermatozoon in the cytoplasm and the absence of immaturity or degenerative alterations. For all ages and with all different sperm types, the fertilization rate after ICSI is reported to be approximately 70–80% (2). This fertilization failure after ICSI may occur because of the following reasons. First, the injected oocyte may fail to initiate the biochemical processes necessary for oocyte activation (3). Second, the biochemical processes are initiated, but they may not occur normally, thus leading to incomplete activation. Third, the spermatozoon may remain poorly accessible to oocyte factors required for chromatin decondensation and formation of the male pronucleus (4). Finally, the procedure used for ICSI may induce subtle structural changes in the organelles of the oocytes, which are undetectable by light microscopy. Although failed fertilization in some of the injected metaphase II (MII) mature oocytes is quite common, total fertilization failure (TFF) after ICSI is distressing for the infertile couple as well as for the fertility professionals.

TFF is a rare event in cases with normal oocytes and spermatozoa (5), and few patients may experience repeated TFF despite normal sperm parameters and a good ovarian response (6). In such cases, the primary reason for failed fertilization after ICSI is the lack of oocyte activation (7). Oocyte activation involves a complex series of events that result in the release of cortical granules, activation of membrane ATPase, meiotic resumption, and the formation of the male and female pronuclei with the extrusion of the second polar body. The oocyte is activated when the spermatozoon enters by either natural fertilization or ICSI. When a spermatozoon comes in contact with the oolemma and penetrates the ooplasm, intracellular calcium oscillation occurs, and this increase in calcium concentration induces oocyte activation and the initiation of zygote development (8). Several authors have proposed different techniques of artificial oocyte activation. Some assisted activation treatments, such as puromycin (9), promote an increase in the intracellular free calcium concentration by releasing calcium from cytoplasmic stores; other activation treatments, such as electrical stimulus (10), promote the influx of calcium from the extracellular medium. Positive results have been obtained by using a combination of calcium ionophore and puromycin (11). Similar to other new assisted reproductive procedures, the impact of either electrical or chemical oocyte activation on the health of the embryo must be evaluated by conducting larger studies, before they can be considered for routine clinical purposes.

For the typical patient who fails to achieve fertilization with ICSI, models proposed to explain why fertilization failed may be less helpful than the counseling requested regarding future treatment. Unfortunately, the efficacy of subsequent infertility treatments following TFF after ICSI remains largely unknown. Therefore, one aim of this study was to develop information that would be useful in counseling patients who experienced TFF with ICSI.

CASE REPORT

A 39-year-old woman and her 45-year-old husband were referred to our clinic for unexplained infertility; they had been married and trying to conceive for more than 2 years. Her physical and gynecological ex-

aminations revealed normal results, including hysterosalpingography and routine blood tests. Her menses were regular. However, her anti-mullerian hormone serum concentration (0.82 ng/ml) and antral follicle count (6) were indicative of low ovarian reserve. Other blood hormone concentrations were within the normal ranges (day 3 follicle-stimulating hormone (FSH) 7.01; thyroid-stimulating hormone 1.1 mUI/ml; prolactin 22.8 ng/ml). The mean sperm parameters were as follows: volume 2.7 ml; count 50.53×10^6/ml (1 specimen had relatively low numbers); motility (A + B) 42.0%, and normal morphology 7.0%.

First, we advised them regarding the optimal timing for intercourse, and, after 3 months, we administered 4 cycles of stimulated intrauterine insemination (IUI), which were unsuccessful. Subsequently, after obtaining informed consent, we offered IVF to the couple. In May 2012, the couple underwent their first IVF cycle. A long GnRH agonist protocol was applied at a daily low dose of 0.05 mg (Gonapeptyl®; Ferring, Switzerland) starting from day 21 of the previous cycle. Ovarian stimulation was achieved using a combination of recombinant FSH and recombinant luteinizing hormone (rLH), to a total dose of 300 IU FSH and 75 IU LH per day (Gonal F® and Pergoveris®; Serono, Switzerland). An injection of 250 mcg (6500 IU) of recombinant human chorionic gonadotropin (hCG, Ovitrelle®; Serono, Switzerland) was administered when the leading follicle reached a mean diameter of 20 mm. Transvaginal ultrasound-guided needle aspiration of oocytes was performed 36 h after the hCG injection. All oocyte-handling procedures were conducted on warm stages (37^oC) using conventional methods. We retrieved 10 oocytes: 8 were mature (MII) and 2 were immature. We performed ICSI for all 8 MII oocytes after a 4-h incubation period. The injected oocytes were cultured for several hours in Cook MINC incubators, which provide a special low-oxygen environment for the embryos; the incubators are supplied by a triple gas mixture containing 5% O_2, 6% CO_2, and 89% N_2, as opposed to the standard air supply, which contains 5% or 6% CO_2 and 20% O_2. Fertilization was assessed 18 h after ICSI by 2 embryologists: none of the 8 injected oocytes exhibited pronuclei, and all were judged unfertilized after a final assessment conducted 6 h later (Fig. 1).

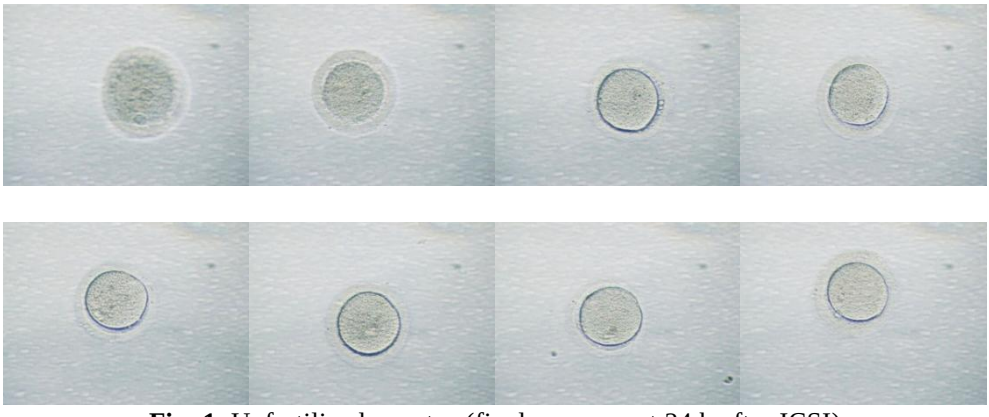

Fig. 1. Unfertilized oocytes (final assessment 24 h after ICSI)

All possible explanations responsible for TFF were analyzed, and all external factors, such as contamination of culture media and improper gamete micromanipulation, were excluded. The lack of fertilization was attributable to the sperm's inability to activate the oocytes, or to the inability of the oocytes to decondense the spermatozoa. However, it was impossible to determine whether the oocytes or spermatozoa were defective as the couple did not agree to an experimental protocol to overcome their complete fertilization block of unknown causes (testing the ability of the husband's sperm to activate mouse oocytes and/or treatment of the patient's oocytes with calcium ionophore in a subsequent ICSI cycle were proposed). After 6 months, the patient asked for a consultation for 6-weeks amenorrhea and a positive pregnancy test. The transvaginal ultrasound examination revealed an ectopic gestational sac, and the patient underwent operative laparoscopy. Surgical findings were as follows: small amount of blood in the peritoneal cavity, bloated right fallopian tube, normal uterus and ovaries, and normal left fallopian tube. After the surgical removal of the right fallopian tube, the patient's recovery was uneventful. A subsequent histological examination of the removed block confirmed the diagnosis of a tubal pregnancy.

DISCUSSION

In this contribution, we describe the case of an infertile couple with unexplained TFF with ICSI. As all 8 oocytes were mature, with no morphological anomalies, and for the ICSI procedure only motile spermatozoa were used, concerns regarding possible technical errors were raised. The risk of oocyte damage by the ICSI procedure is low in humans and may be related to both the skill of the person performing the injection procedure and to the quality and quantity of the gametes used during the procedure. The embryologist conducting the ICSI procedure is a significant predictor of fertilization, whereas laboratory conditions such as the type and model of incubators and culture of oocytes (individually versus grouped) do not affect the fertilization rates (12).

Although ICSI is now considered a routine procedure, it remains a very demanding technique to master, partly due to its inherent technical difficulty and partly due to the heterogeneity of the cases. It is generally agreed that the ICSI procedure is subject to a learning curve. One common technical failure may result in the spermatozoon not being deposited within the cytoplasm of the oocyte. In this situation, the oocyte membrane may not have been broken while attempting to aspirate the ooplasm into the ICSI needle. Thus, the spermatozoon is then deposited next to the oocyte membrane, so that when the oolemma returns to its original position, the spermatozoon is pushed out into the perivitelline space (Fig. 2A), or is trapped inside a sac formed by the membrane (Fig. 2B). The spermatozoon may also adhere to the tip of the injection needle or remain within the injection needle and be inadvertently pulled out upon withdrawal of the needle from the cytoplasm. The degeneration of oocytes after ICSI is often a result of a faulty ICSI technique, e.g., use of an injection pipette that is too large or not sharp enough. Aspiration of the ooplasm is always performed to ensure that the oocyte membrane is broken during injection. However, if excessive ooplasm is aspirated, the oocyte frequently degenerates (Fig. 2C).

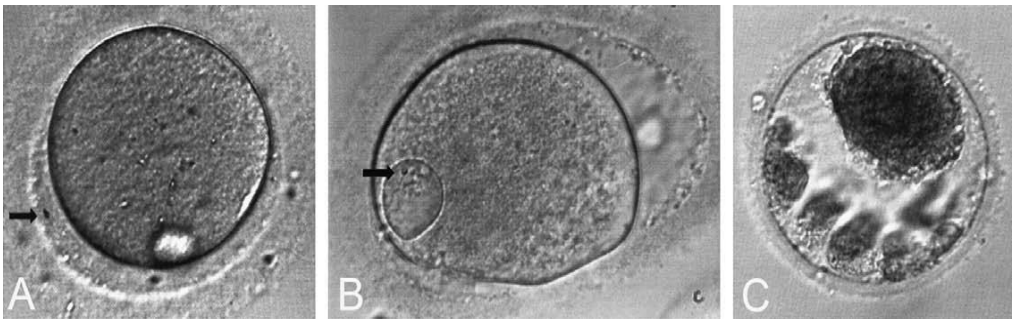

Fig. 2. Damaged oocytes during ICSI (A-spermatozoa in perivitelline space; B-spermatozoa trapped inside a membrane sac; C-degenerated oocyte after excessive cytoplasm aspiration)

None of the previously described aspects were found in this case. When fertilization failure occurs in most or all of the injected oocytes, despite the procedure being performed by experienced practitioners using normal spermatozoa, TFF is attributable to oocyte dysfunction, oocyte activation failure, or inability of the spermatozoon to be decondensed and processed by the oocyte.

Despite frequent use and success of IVF treatment for infertile couples, cases of TFF continue to be encountered. Their consequences are devastating to the patients, with lost resources, incurred costs, and much distress. Understanding the etiology of FF is, therefore, of critical importance to assist patient counseling and optimize treatment.

The incidence of TFF after conventional IVF using sperm of normal quality has been reported to range from 5% (13) to as high as 15–20% (14). While ICSI has overcome many fertilization problems, it does not completely eliminate TFF. In a randomized clinical trial comparing outcomes after ICSI or IVF for cases of non-male factor infertility, Bhattacharya et al. (2001) documented a TFF rate of 2% versus 5% for ICSI and IVF, respectively (15). Indeed, several large studies using ICSI for a variety of infertility diagnoses reported TFF at rates ranging from 1.3% in 1779 cycles(16) to 3% in 2732 cycles (17). The possible etiologies underlying TFF are complex and may relate to the cycle-specific parameters, yield and quality of oocytes, availability of motile sperm, and/or to severity of sperm defects (18, 19, 20). Sperm abnormalities may result in abnormal sperm decondensation and/or aberrant pronuclear development, migration, apposition, and first mitosis (21). Some ICSI oocytes fail to activate, which, under some circumstances, has been successfully overcome by manipulating intracellular calcium levels in oocytes by using calcium ionophore (22) or electric pulses (23). Several early studies concerning gamete ultrastructure (24) and staining of DNA or whole chromosomes (25) led to the identification of abnormal chromatin patterns and/or chromosome numbers, of either paternal or maternal origin, in non-fertilized oocytes. Recent studies of microtubules also revealed abnormal spindle and interphase microtubules, indicating that defects in cytoplasmic components of oocytes may be the main cause of failed fertilization (26).

This case was extremely challenging

from a counseling perspective. For couples experiencing TFF after ICSI, little data exists for patient counseling, especially with respect to the efficacy of continued therapy and the future hope of a successful live birth. To date, only 2 studies have analyzed the outcome of a subsequent conventional ICSI cycle after a previous TFF. In 1 study (published in 2003), TFF reoccurred only once in 23 repeated ICSI cycles; the mean cycle fertilization rate in that population was 69.2%, and the clinical pregnancy rate per transfer was 45.4% (27). In the other study (published in 1995), TFF reoccurred in 5 of the 27 repeated cycles (17). The differences between fertilization rates remain unexplained, although fluctuations in gamete quality may play a contributory role. A history of failed fertilization may be related to a gamete abnormality that may be modified or corrected during the next cycle. Pretreatment endocrine assays and semen analyses have proven to be of little value in predicting failed fertilization. Very subtle improvements in semen parameters and/or oocyte yield/quality may result in fertilization during a subsequent ICSI attempt. Otherwise, the options of donor sperm insemination, donated oocytes or embryos, adoption, and remaining childless should be discussed with the couple (28).

CONCLUSIONS

Despite the important advances in assisted reproductive technologies, successful fertilization for every patient is not guaranteed, even with ICSI. In such cases, new laboratory techniques can aid a subsequent ICSI cycle. However, from a practical point of view, especially in patients with normal sperm parameters, conventional ICSI can be considered a good alternative. It is important to note that no unified theory exists to explain the phenomenon of TFF, since it might be the result of multiple, and, as our case shows, sometimes, temporary anomalies. Therefore, for couples with unexplained infertility (normal sperm parameters and optimal ovarian response) and TFF after ICSI, a subsequent treatment cycle with conventional IVF or split ICSI/IVF may be recommended.

SCHIZOPHRENIA AND VIRUS-GENES INTERACTION

Schizophrenia is a severe mental disorder, which affects approximately 1% of the global population. The disease is caused by genetic and environmental factors as well as gene–environment interactions. An international study conducted by Borglum and colleges show that interaction between genes and cytomegalovirus (CMV) influences the risk of developing schizophrenia. Women that have been infected by the virus will have an increased risk of giving birth to a child who later develops schizophrenia, if the child has the gene variant associated with this mental disorder. By using single nucleotide polymorphisms (SNP), the researchers have showed a strong association between schizophrenia and a number of loci such as: SNP rs4757144, located in an intron of the circadian rhythm-associated gene *ARNTL* on 11p15, SNP rs8057927 in the intron of gene *CDH13* on 16q23 (both genes previously linked to schizophrenia or other psychiatric disorders) and, for first time, one region at chromosome 10p11 overlapping the gene *ZEB1*. This study also identified a significant interaction between maternal CMV infection and *CTNNA3* of the progeny, a gene that has not previously been associated with schizophrenia. The results emphasize the importance of environmental factors in disease development. These results may suggest also that a vaccine against CMV may help to prevent schizophrenia (Borglum AD, Demontis D, Grove J, Pallesen J *et all*. Genome-wide study of association and interaction with maternal cytomegalovirus infection suggests new schizophrenia loci. *Mol Psychiatry*. 2013 Jan 29).

LOCAL PERIPROSTATIC ANESTHESIA BETWEEN OPTION AND NECESSITY IN TRANSRECTAL ULTRASOUND-GUIDED PROSTATE BIOPSY (Abstract) According to the European Association of Urology guidelines, local periprostatic anesthesia during ultrasound guided biopsy is "state of the art" without specifying the exact benefits and character of choice vs. necessity of this maneuver. **Aim:** To determine the benefits of using periprostatic anesthesia as standard method of analgesia in patients undergoing transrectal ultrasound guided prostate biopsy. **Material and methods:** We conducted a prospective randomized study involving 100 biopsy patients. The patients were randomized in two groups, 50 patients benefiting from local periprostatic anesthesia with 10 ml of lidocaine and the remaining 50 without local anesthesia. In our clinic we use the 12-core prostate biopsy procedure using 18G/20 cm caliber needles. To assess perceived pain intensity during the procedure, immediately after biopsy we applied to patients a VAS questionnaire (Visual Analogue Scale) as a simple method of quantitative evaluation of a symptom the perception of which varies greatly between individuals. **Results:** A reduction in perceived pain by 45.06% (30.47 vs. 16.74) was recorded in the group receiving local periprostatic anesthesia. It is also worth mentioning that the patients receiving anesthesia said that anesthesia punctures were the most painful (the remaining punctures being much less painful), while patients without anesthesia reported pain intensity levels more or less equal in all 12 performed punctures. **Conclusions:** Local anesthesia is a necessity in ultrasound guided prostate biopsies as it significantly reduces pain intensity in patients undergoing this diagnostic procedure. **Keywords:** PROSTATE BIOPSY, LOCAL ANESTHESIA, PAIN.

The European Association of Urology guidelines state that local periprostatic anesthesia during the ultrasound guided biopsy is a "state of the art" method without specifying its exact benefits and choice vs. necessity of this maneuver (1). Consequently, we decided to conduct a comparative study in patients who already underwent an ultrasound guided transrectal prostate biopsy in an effort to demonstrate whether local periprostatic anesthesia with lidocaine 1% (2) has advantages or not

over no anesthesia in relation with perceived pain during core biopsy.

MATERIAL AND METHODS

In the interval May 21, 2010- October 29, 2012, at the Urology Clinic of the „C.I. Parhon" Hospital in Iaşi, 300 ultrasound guided transrectal prostatic biopsies were performed. The study was conducted on 100 patients who underwent biopsy in the interval September 23, 2010- August 25, 2011 with the purpose of determining whether local periprostatic anesthesia is a state of the art method or a necessity in ultrasound guided transrectal prostatic biopsy.

In our clinic we use the 12-core prostate biopsy procedure (fig.1) using 18G/20cmcaliber needles (fig.2) (3,4,5). For guiding we use a BK Pro Focus UltraView ultrasound equipped with an endorectal transducer allowing the simultaneous visualization on the screen of the transverse and longitudinal planes (fig. 3). This type of visualization facilitates the precise identification of all prostate regions and especially the accurate location of puncture trajectory in different zones of the prostate, thus simplifying the punctures and allowing a high standardization of the biopsy scheme.

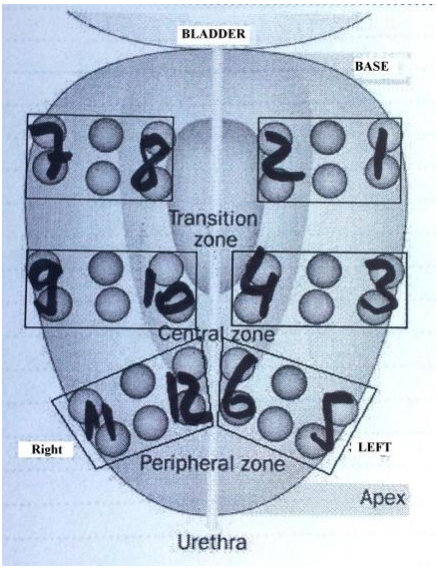

Fig. 1. 12-core biopsy scheme

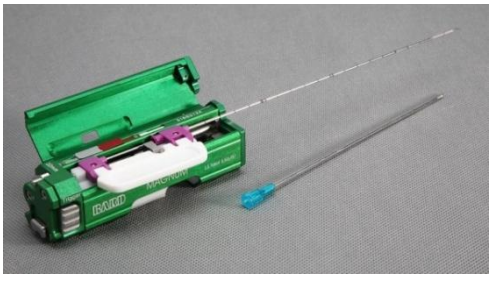

Fig. 2. Biopsy gun with a fixed needle

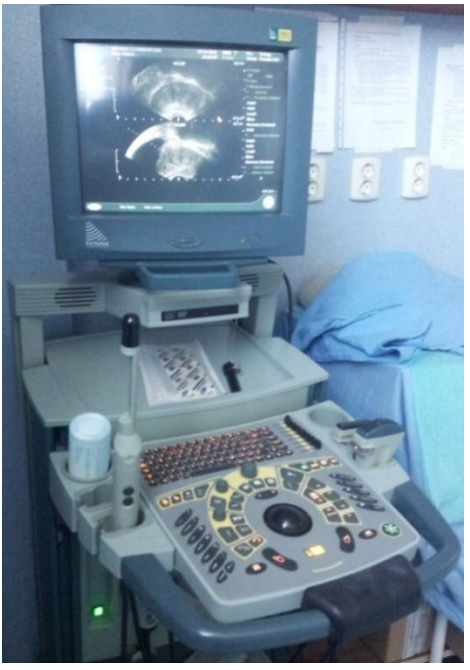

Fig. 3. BK Pro Focus UltraView ultrasound

Also, minimal analgesia with 1 vial of Ketorol and 1 vial of Algocalmin administered 30 minutes before the puncture is provided in all patients.

The study was conducted on a randomized group of 100 patients: all of them were

given the above mentioned minimal analgesia and 50 were also given a periprostatic 10 ml injection of lidocaine (5 ml per side) (6, 7).To assess perceived pain intensity during the procedure, just after biopsy the patients were asked to fill-out a Visual Analogue Scale questionnaire (VAS) as a simple method of quantitatively evaluating pain perception which varies greatly between individuals (fig. 4).

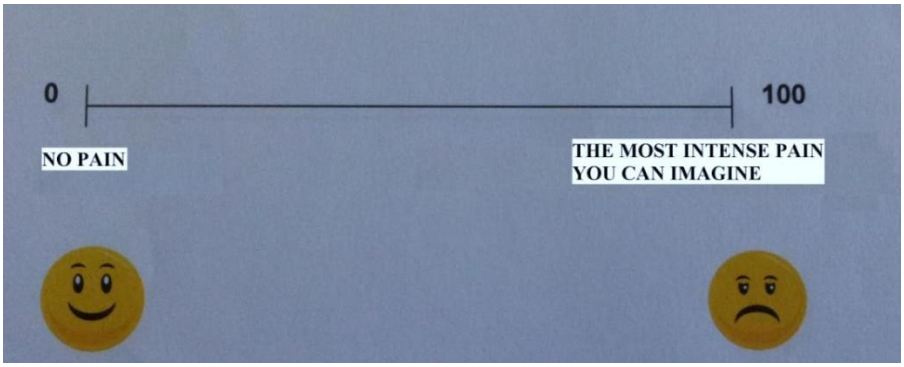

Fig. 4. Visual Analogue Scale (VAS)

The advantage of using VAS is that pain is measured on a 0-100 scale, thus being more sensitive to small variations. Furthermore, the method can be easily explained to patients, who have no problem in understanding the relatively simple manner of rating pain. The scale gives a quantifiable number reflecting the pain perceived by the patient (8).The questionnaire was applied immediately after the completion of the procedure in order to obtain a more accurate evaluation of pain intensity. The patients were asked to rate perceived pain intensity over the whole procedure. This prevented us from strictly assessing the pain felt during biopsy punctures, but added validity to the evaluation of the same type of pain in all patients by the fact that the comparison of the obtained scores is possible and the obtained results reliable. These obstacles arise every time in studies evaluating the perceived level of pain and comparing it between different groups of persons. The difficulty stems from the major differences in pain perception between persons and also from the way pain is defined in relation with a person's social status, physio-pathological history and even professional training (9).

The obtained ratings were added up, an arithmetic average was calculated for each group, and then comparisons were made (tab. I).

TABLE I

Results of the study groups

Groups of patients	**Periprostatic anesthesia**	
	With	**Without**
Number of patients	50	50
Average VAS value	16.74	30.47
Extreme VAS value	0 – 39	2 – 82

In the group with local periprostatic anesthesia a decrease in the perceived pain level by 45.06% (30.47 *vs.* 16.74) – value p 0.00064, was noticed. Furthermore, the patients who received periprostatic anesthesia reported anesthesia punctures as being

more painful (the remaining punctures being less painful), while the patients on no periprostatic anesthesia reported a more or less equal level of pain intensity in all 12 punctures performed. Results distribution shows that in the group with periprostatic anesthesia the highest values of perceived pain intensity were much lower than in the group with no periprostatic anesthesia (82 *vs.* 39) and that there were less VAS scores below 20 in the group with no periprostatic anesthesia (18 patients), while the periprostatic anesthesia group frequently presented VAS scores below 20 (32 patients) (fig. 5).

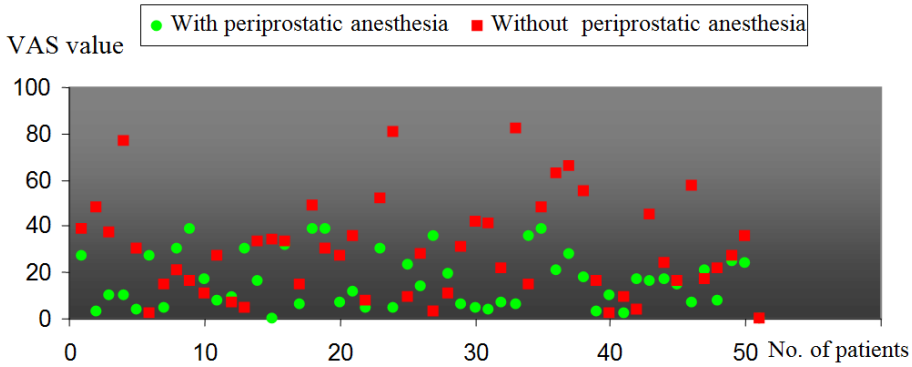

Fig. 5. Distribution of VAS obtained values

CONCLUSIONS

The obtained results are in favor of periprostatic anesthesia regardless of the analysis method. Nevertheless, we need to mention that the only reliable method for statistically analyzing the data obtained by VAS in view of qualitative comparison of groups of persons is represented by the arithmetic average of all obtained ratings. VAS does not provide accurate information when patients are compared individually due to the high degree of subjective rating and difficulty in measuring pain. However, comparing the average scores of the two groups we feel entitled to state that local periprostatic anesthesia is a necessity in ultrasound guided prostate biopsy, significantly reducing perceived pain in the patients undergoing this diagnostic procedure. Under these conditions, as a result of this study we have adopted local periprostatic anesthesia with lidocaine as a mandatory standard method in transrectal ultrasound guided prostate biopsy protocol.

TIME TO OFFER A POLYPILL TO PEOPLE AGED 50 OR OVER?

In David S. Wald and his coauthors study, the clinical and academic aims are to bridge the interventional and preventive approaches to cardiovascular disease. He coordinates the Polypill Prevention Programme, a novel service that adopts the polypill approach in coronary heart disease and stroke prevention. The concept of a "polypill" as a tablet or capsule consisting of a combination of drugs to simultaneously reduce several cardiovascular risk factors first captured worldwide attention in 2003. Suggested components for this initial polypill were aspirin, a statin, 3 blood pressure-lowering drugs at half the standard dose (eg, a thiazide, an angiotensin-converting enzyme [ACE] inhibitor, and a calcium-channel blocker), and folic acid. Since that time, several polypill formulations have been manufactured and tested in clinical trials for primary and secondary prevention of cardiovascular disease. Some are already commercially available in India. The clinical trials demonstrated the feasibility and safety of a polypill in lowering blood pressure and low-density lipoprotein (LDL) cholesterol levels in people with 1 or more cardiovascular disease risk factors, although these effects were generally less than predicted from early research. The use of a polypill in the primary prevention of cardiovascular disease has been a focus of research at the Wolfson Institute, where the inventors of the polypill work. A Polypill Prevention Programme was established in 2006 to provide a service applying the polypill approach to the prevention of first heart attacks and stroke; separate component drugs were used at the correct doses, because a single polypill was not yet available. Using a randomized, double-blind, placebo-controlled, crossover design, they were able to estimate risk factor reductions with the polypill more accurately than in previous polypill trials, which used a parallel-group design. The polypill consisted of amlodipine 2.5 mg, losartan 25 mg, hydrochlorothiazide 12.5 mg, and simvastatin 40 mg, and was manufactured for the study by Cipla (Mumbai, India). For the first time in a study of the polypill, the only criteria for participation were age (≥50 years) and no history of cardiovascular disease. Using the observed reductions in blood pressure and LDL cholesterol and evidence of the quantitative relationship between risk factors and risk, Dr. Wald and his coauthors calculated that this polypill would result in reductions of 72% for ischemic heart disease events and 64% for strokes. These results were greater than those in earlier trials.No serious adverse events were reported during the study (Wald DS, Morris JK, Wald NJ. Randomized polypill crossover trial in people aged 50 and over. *PLoS One*. 2012;7: e41297).

MANAGEMENT OF BORDERLINE OVARIAN TUMORS (Abstract): Borderline ovarian tumors are an intermediate stage between benign cystadenomas and adenocarcinomas. **Aim:** The paper evaluates the management of borderline ovarian tumors (BOTs) in the patients admitted and treated in our clinic in the interval January 2003 – June 2011. **Material and methods:** The observation sheets and pathology results of 264 patients with malignant ovarian tumors were analyzed. **Results:** Of the 264 malignant ovarian tumors 74 (28.03%) were low malignant potential. Patients with BOT were aged 18-72 years (mean 46 ± 6.2 years) and those with invasive tumors 14-83 years (mean 53 ± 9.8 years). 92.18% were in stage I. Sixty tumors were graded G1. 53.52 % of the tumors were over 10 cm (maximum 30 cm) in size. The histological types were: serous – 35 cases, mucinous – 19 cases, mixed (serous and mucinous) – 8 cases, and endometrioid - 2 cases. Fifteen patients presented intraepithelial carcinoma and 11 noninvasive implants into the peritoneal cavity. Five women had recurrences. **Conclusions:** Ovarian borderline tumors with histological characteristics of carcinoma, but with good behavior are now with better defined histological features. The biggest challenge in the management of women with these tumors is to identify the subset that will behave in a malignant fashion and to develop effective treatment for them. **Keywords:** BORDERLINE OVARIAN TUMOR, TREATMENT, TUMOR PROGRESSION

BOTs behavior is enigmatic, pathogenesis unclear and clinical management controversial, especially for serous borderline tumors. From oncologic point of view there are numerous debates on the surgical treatment of these patients, taking into account fertility sparing and outcomes. So the question was raised if BOT patients are not in general overtreated, and on the other hand how can the patients at high risk be distinguished?

MATERIAL AND METHODS

In the interval January 2003 – June 2011, 264 women with ovarian cancer were treated surgically in our clinic. During this interval we reviewed the medical records and pathological findings of the patients with BOTs. Histological criteria of inclusion in this category of tumors were: proliferative activity of epithelial cells (epithelial multi-layering of more than 3 layers, loss of cell polarity), no more than 4 mitoses/10 HPF (high power field), moderate to marked nuclear atypia (nuclear pleomorphism), increased nuclear/cytoplasmic ratio, slight-to complex branching of epithelial papillae, detached cellular clusters in the glands, and absence of frank stromal invasion (the most important criterion of

diagnosis). The patients were followed-up until June 2012. We tried to establish all parameters which must be taken on consideration for a good management decision.

RESULTS

74 (28.02%) women had BOTs. The mean age of the BOT patients was 46±6.2 years (range 18-72 years) as compared to 53±9.8 (range, 14-83 years) in the women with invasive ovarian carcinoma.

The average size of the tumors was 10 cm, in 53.52 % of the patients being over 10 cm (maximum size 30 cm). The largest were more frequently mucinous BOTs. As to pathological type, 35 (54.68 %) were serous tumors (fig. 1), 19 (29.68 %) mucinous tumors (fig. 2, 3), 8 (12.5 %) mixed (serous and mucinous), and 2 (3.14 %) endometrioid (fig. 4). Serous BOTs were bilateral in 4 cases.

A particular variant of BOT is serous carcinoma with micropapillary architecture, a highly aggressive variant with a bad course as compared with BOTs in general, but with a better prognosis than invasive ovarian cancer. Seven of our patients had this variant. Micropapillary pattern is usually associated with the risk of invasive implants. To complicate the pathological notion of BOT, in the last few years, the presence of one or more discrete foci of stromal microinvasion (less than 3 mm in diameter and smaller than 10 mm²) was included in the category of BOTs as intraepithelial carcinoma. Of our study patients 14 presented intraepithelial carcinoma (fig. 5 a, b, c, d).

d. Intraepithelial microinvasion

Fig. 5. Transition from cystadenoma to BOT and intraepithelial microinvasion

Peritoneal dissemination of BOT is called implants and not metastasis, because even the women with extraovarian disease have a good course. These implants are an important component of staging, and are in fact the most important prognostic indicator. They are classified as "invasive" and "noninvasive" based on their microscopic appearance, and the noninvasive ones are subdivided into epithelial and desmoplastic. Invasive implants are characterized by cellular atypical, a haphazard and disorderly infiltration of normal tissues, histological resembling a low-grade serous adenocarcinoma. In contrast with the well-defined limits of desmoplastic implants, the invasive implants exhibit irregular borders. Eleven (17.18%) of our study patients had noninvasive peritoneal implants from serous BOT.

Mucinous BOTs are in general unilateral. There are two types: intestinal-type (more frequent) and endocervical-like (with risk for recurrence and death). When present on both ovaries and as advanced stages they may be primary from the ovaries, but more often metastatic from the digestive tract. Immunohistochemistry (IHC) using cytokeratines is of benefit in the differential diagnosis of primary ovarian carcinoma from metastatic intestinal adenocarcinoma. *Pseudomixoma peritonei* is almost always the result of intraperiotoneal dissemination of a non-ovarian mucinous neoplasm, especially from appendicle tumors. In our study there were 2 cases with *pseudomixoma*

peritonei.

Only 4 women were in stage II, the others being in stage I – 93.55 % (fig. 6, 7, 8 a,b). Fifty-one tumors were G1.

Primary treatment for BOTs is surgery. Total abdominal hysterectomy with bilateral salpingo-ooforectomy, peritoneal cytology, multiple peritoneal biopsies is the golden standard in women in peri- and postmenopause, those who completed childbearing or do not want to preserve the fertility. Appendicectomy is a particular procedure, necessary in cases with mucinous tumors. Because BOTs are frequent during the reproductive period, the diagnosis is made at early stage and women have an excellent prognosis. For that reason the treatment of choice preserves fertility (that means keeping the uterus and part of one ovary at least). Even though the risk of recurrence is substantial after conservative treatment of BOTs, the survival rate is not altered by this approach. The decision of cystectomy instead of adnexectomy depends on such factors as woman's age, desire of childbearing, surgeon and patient expectation before treatment, but clear guidelines do not exist in practice. Usually it is performed a unilateral adnexectomy or associated with cystectomy for the other ovary when BOTs are bilateral. Biopsy of the controlateral normal ovary must be avoided, for protection from adhesions, which could decrease the fertility. None of our patients was treated by laparoscopic surgery. In general we did not perform pelvic and para-aortic lymphadenectomy in patients with BOTs.

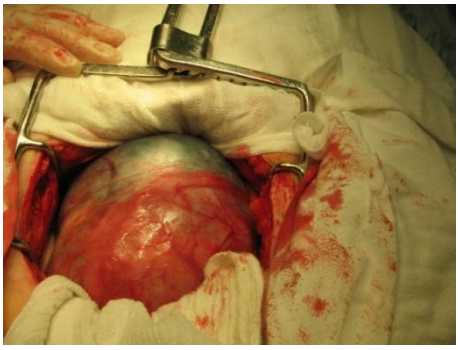

Fig. 6. DE 60 years – stage IA

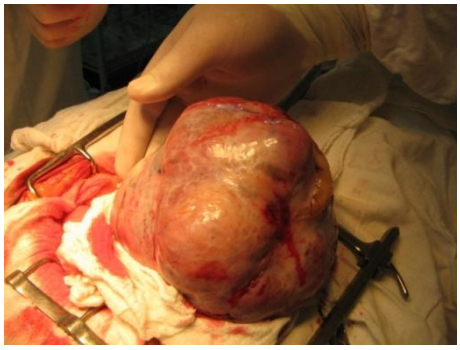

Fig. 7. AT 62 years – stage IA

a.

b.

Fig. 8. CM 30 years– Stage IC (a - during surgery, b - micropapillary aspect)

In the study group there were 5 cases with serous BOT recurrence at 5, 3, 2 and 1 year, respectively from primary surgery. Of the cases with recurrence after 1 year, one had BOT of the other ovary even though she received chemotherapy after surgery, and in the second BOT recurred as invasive ovarian cancer. The problem in these cases is that it could have been some foci of invasive ovarian cancer undetected at the pathological exam after primary surgery (the women received adjuvant chemo one month after diagnosis). The patient with recurrence after 2 years also presented invasive carcinoma and the initial stage was IA without adjuvant treatment.

DISCUSSION

BOTs account for 10-15% of malignant ovarian tumors (1), but in our study they represented 28.03%. Patients, with a mean age of 38 years, are younger than those with invasive carcinoma (2). In our patients mean age was 46 years, but significantly less than of invasive cancer patients. BOTs are epithelial tumors: 50% serous, 46% mucinous, and almost 4% mixed endometrioid, clear cell, or Brenner tumors. In our study series 54.68% were serous BOTs. Bilateral tumors were described in the literature in 25-50% of the cases (3). 90% are typical serous BOTs and 10% micropapillary BOTs progressing to low-grade serous ovarian carcinoma. Of our patients 9.47% had a micropapillary pattern.

20-46% of serous BOTs present peritoneal implants – only 17.18% in our cases. Peritoneal implants may occur in 66% of the patients with exophitic lesions on ovarian surface as compared to 5% of those with endophitic lesions. In 2000, Seidman proposed that since serous BOT with invasive implants have a clinical course similar to a low grade invasive carcinoma with a 34% mortality rate, it is more reasonable to classify these tumors as carcinomas (4). In agreement with FIGO and WHO staging the diagnosis of BOT is made on histological type and not on extraovarian spread. Patients with serous tumors and noninvasive implants have a low rate of recurrence and a survival rate of 100% (5). Unlike noninvasive implants, cases with invasive implants have a rate of recurrence of 45% instead of 11% for a follow-up period of 15 years (6). Micropapillary serous carcinoma (MPSC) has a powerful association with invasive implants and a survival rate at 10 years of only 60% (7). Recurrences occur in 77% of women with invasive carcinoma (2 cases in our study patients), with a high mortality rate until 74% (8). Sometimes pathologists acknowledge the distinction between invasive and noninvasive implants at time can be very difficult. Molecular genetic studies including mutational analysis and allelic imbalance will determine whether different kinds of implants have distinct molecular genetics profiles and whether these profiles can predict outcome. However, till now studies on noninvasive implants alone have been conducted. Allelic imbalance and the KRAS mutation status are similar in BOT and synchronous peritoneal implant in the same patient.

Mucinous BOTs are in 90% of cases unilateral and 85% of them are intestinal-type and 15% endocervical-like (9). Usually mucinous BOTs restricted to ovaries.

The correct diagnosis of BOT through frozen sections gives the surgeon the option to do a conservative treatment. This exam differentiates borderline from invasive ovarian tumors having a sensitivity of 67-97 % and a specificity of 97-100 % (10). Another study indicates a sensitivity of 71.1 %, PPV (positive predictive value) 84.3 %, over-diagnosis 6.6 %, and under-

diagnosis 30.6 % (11). Mucinous tumors and tumors over 10 cm in size are predictors of BOT under-diagnosis. For tumors under 10 cm a minimum of one section/cm of maximum diameter (without cystic areas with smooth wall) and two sections/cm for tumors over 10 cm are recommended.

If cystectomy is performed, the rate of recurrence is higher than in the cases with adnexectomy, 12-58 % vs. 0-20 %. On the other hand, bilateral cystectomy significantly increased the cumulative pregnancy rate without increasing significantly the cumulative recurrence rate (12). But in these women longer follow-up is needed because of the likelihood of late recurrence.

Pelvic and para-aortic lymph node involvement in women with serous BOTs seems to be present in 7-23 % of the cases with lymph node biopsy at the time of surgery (13). Lymphadenectomy is not necessary for disease staging, and when done it usually does not significantly improve the course. Recent studies show that lymphadenectomy can be avoided even in advanced BOTs stages because it does not influence recurrence and survival rate (14, 15). So, in BOTs lymphadenectomy is limited to research.

Fertility outcome in women with conservative treatment for BOTs is good and spontaneous fertility rate varies between 32 % and 65 % (16). But these patients frequently need ovarian stimulation for having a pregnancy. The next question is if ovarian stimulation is an option in these women given the debates regarding the link between ovarian stimulation and the risk for ovarian cancer. A multicentre retrospective study on 30 patients with a history of BOTs that underwent infertility treatment found recurrences in only 4 of them (16 %) 93 months after the treatment for BOT and 43 months after ovarian stimulation. The conclusion is that in women with early stage BOTs ovarian stimulation is safe (17). The need for completion surgery as a usual practice is disputed and depends of some factors (histological subtype, stage, type of conservative treatment and patient preference). But the number of patients which choose definitive treatment soon after finishing family planning is high because of psychological stress.

The 5-year survival rate in patients with stage I BOTs is 95-97 %, but at 10 years only 70-95 % because of late recurrences. Chemotherapy regimes are similar with those for invasive epithelial ovarian cancer. Clinical trials are needed for getting a clear opinion on the role of chemotherapy in BOTs.

Tumor DNA ploidy could be used for the identification of patients which will develop an aggressive disease (with tumor aneuploidy). Adjuvant therapy is not indicated for stage I diploid tumors (18). Also the presence of BRAF (codon 599) and KRAS (codon 12 and 13) in serous tumors and KRAS mutations in mucinous tumors is associated with tumor proliferations (19). These mutations are involved in early tumorigenesis, but the mutation is not sufficient for malignant transformation. KRAS and BRAF mutations are rare in high-grade serous carcinomas, different from p53 mutation which is present in more than 50% of high-grade carcinomas, and is rare in BOTs and low-grade carcinomas.

CONCLUSIONS

The mean age of the BOTs patient was 46±6.2 years, less than those with invasive ovarian carcinoma.

The presence of extraovarian implants - 11 of our study patients and the micropapillary type -7 from our cases are a challenge for gynecologists.

Given patients' age and the need of fertility

sparing, their intraoperative assessment by peritoneal washing, ooforectomy for the affected ovary, infracolic omentectomy and multiple peritoneal biopsies is very important.

The opportunity of adjuvant CHT is a matter of dispute, especially for patients with invasive implants associated with micropapillar architecture.

CORRELATION BETWEEN ADIPONECTIN, LEPTIN, INSULIN GROWTH FACTOR-1 AND BONE MINERAL DENSITY IN PRE AND POSTMENOPAUSAL WOMEN

Corina Morcov (Buța)[1], Carmen Vulpoi[2], D. Brănişteanu[2]

1. Ph.D. student at University of Medicine and Pharmacy „Grigore T. Popa" - Iasi

CORRELATION BETWEEN ADIPONECTIN, LEPTIN, INSULIN GROWTH FACTOR- 1 AND BONE MINERAL DENSITY IN PRE AND POSTMENOPAUSAL WOMEN (Abstract): Body weight positively correlates with bone mass, gravity being a stimulating bone stress. Adipose tissues could influence bone metabolism especially in postmenopause. Also, muscle mass positively correlates with bone mass and is dependent on physical activity, but also on some hormones with direct effect on bone, such as insulin growth factor-1(IGF-1). **Aim**: Our study investigated the relative influence on lumbar bone mass of pre and postmenopausal women of body weight, leptin, adiponectin and IGF-1. **Material and methods**: Cross-sectional study including six groups of 8 to 15 pre and postmenopausal healthy volunteers with different weight; body mass index (BMI): normal and underweight (BMI<25 kg/m^2), overweight (BMI 25-30 kg/m^2), and obese (BMI>30 kg/m^2). Lumbar bone mineral density (BMD) and body composition (BC) were evaluated by dual X ray absorptiometry (DXA, Hologic), while serum leptin, adiponectin and IGF-1 were measured by ELISA. **Results**: Body weight, fat and lean mass positively correlated with BMD, irrespective of age ($p<0.05$, ANOVA). Leptin was an independent predictor for bone mass only in postmenopausal women ($p<0.05$). Adiponectin negatively correlated ($R2=0.1975$) and IGF-1 positively correlated with body mass ($p<0.05$). **Conclusions**: Increased body weight prevents bone loss after menopause. Leptin and IGF-1 have adjacent positive roles in preserving bone mass during postmenopause. **Key words**: BODY COMPOSITION, LEPTIN, ADIPONECTIN, IGF-1, MENOPAUSE.

In recent years, many studies have been published showing the link between bone mass, body composition, and hormonal parameters. Their conclusions are: body weight has an important predictive effect on bone mass; body weight influences bone mineral density through both fat mass and lean mass; fat mass acts through several mechanisms, once through the pressure it exerts on the skeleton, then by its association with bone active hormones secretion, estrogen and leptin secretion by adipocytes (1), muscle mass is dependent not only on physical activity but also on hormones, such as IGF-1 and testosterone, that have a direct effect on bone (2).

MATERIAL AND METHODS

Cross-sectional study on 6 groups of about 8 women each. Age dstribution: 31

premenopausal women and 37 postmenopausal women (at least two years of menopause). BMI: normal and underweight (BMI<25 kg/m^2), overweight (BMI 25-30 kg/m^2) and obese (BMI>30-40 kg/m^2). Age-group and BMI distribution: premenopausal women 16 normal weight and underweight, 9 overweight and 6 obese; postmenopausal women: 8 normal weight and underweight, 11 overweight and 17 obese. All women volunteered to participate in this study, and were recuited into the study from patients, students and staff of Iasi County „St. Spiridon" Emergency Hospital. A signed informed consent was obtained from all women.

Exclusion criteria were: diabetes mellitus, osteoporosis under treatment, hormone replacement therapy, severe liver or kidney disease, hyperthyroidism, primary hyperparathyroidism, hypogonadism, growth hormone deficiency, Cushing's syndrome, corticotherapy for over a year, anorexia nervosa, malabsorption syndrome, genetic syndromes. A fasting blood sample was collected, centrifuged, and stored in a refrigerator (-30° C) for estrone and estradiol determinations. Then, all volunteers' height and weight were measured, and subjected to osteodensitometry by dual X-ray absorptiometry (DXA). A certified technician measured bone mineral density (BMD) of the lumbar spine on Hologic DXA. Total fat and lean masses were expressed in grams. Lumbar BMD was expressed in g/cm^2. Leptin (ng/ml), adiponectin (mg/l), IGF-1(μg/l) were determined using commercial ELISA kits (Diagnostic Automation Inc., Calabasas, CA). The results were statistically processed using NCSS 2007 software, simple Pearson correlation, student t test, the correlation being considered significant when $p<0.05$. Multivariate regression (ANOVA) was used to exclude systematic biases.

RESULTS

Lumbar BMD was significantly lower in all postmenopausal women regardless of body weight compared with premenopausal women ($p<0.05$). We found that lumbar mineral density in obese postmenopausal women was similar to that in obese premenopausal women, while normal weight or underweight postmenopausal women had a significantly lower BMD than premenopausal women ($p<0.05$) (fig. 1).

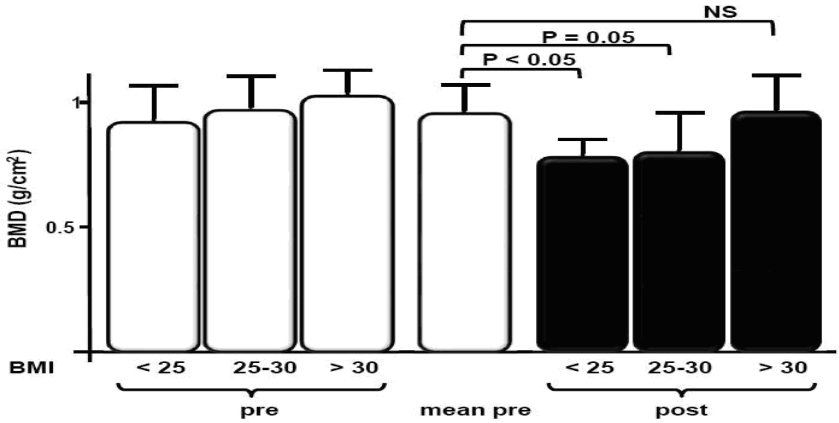

Fig. 1. Mean lumbar bone mineral density of premenopausal (left) and postmenopausal (right) women

BMD in lean postmenopausal women was significantly lower than in premenopausal women ($p<0.05$). BMD in obese postmenopausal women was comparable to that of premenopausal women.

Body weight, expressed as BMI (kg/m^2), positively correlated with lumbar BMD, Z score for all women (fig. 2).

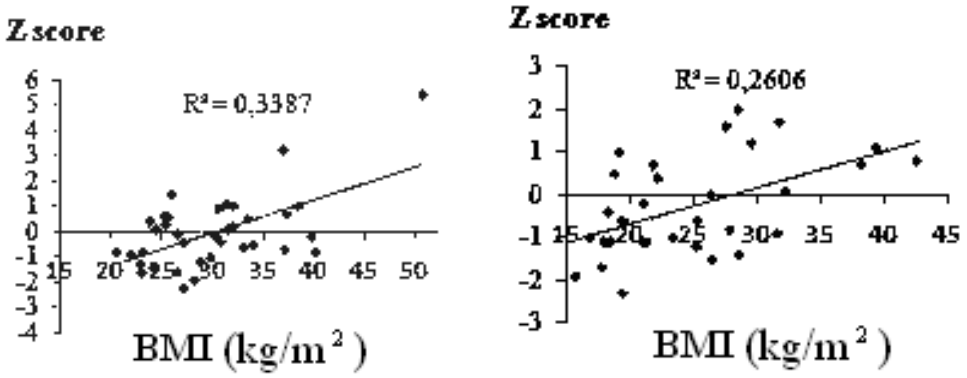

Fig. 2. Relation between lumbar Z score and BMI in premenopauzal women (right) and postmenoausal women (left)

Leptin positively correlated with fat mass, while between leptin and Z score there was a significant correlation in all study groups, suggesting that leptin itself may have direct effect on bone ($p<0.05$, fig. 3).

IGF-1 correlated positively with bone mineral density in premenopausal women ($r^2=0.1854$, $p<0.05$), while adiponectin correlated negatively ($r^2=0.1975$) (fig. 4, 5).

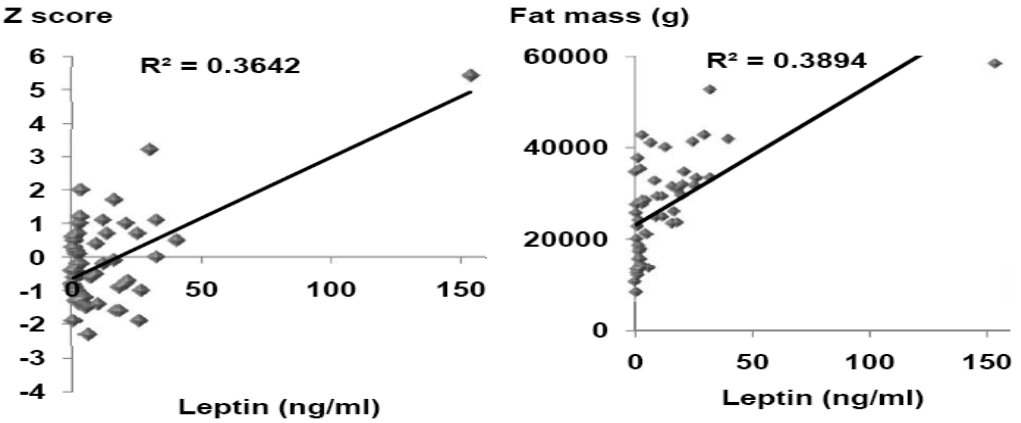

Fig. 3. Correlation between leptin and lumbar Z score (right), and between leptin and lean mass (left)

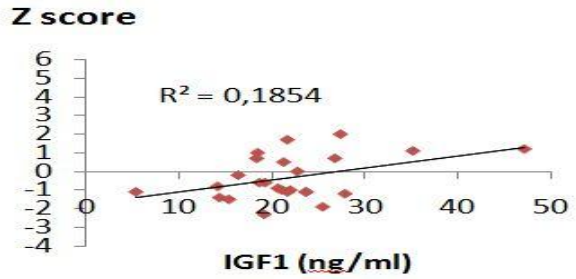

Fig. 4. Positive correlation between IGF1 and lumbar Z score

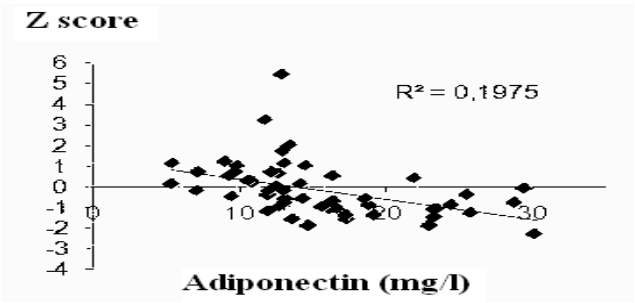

Fig. 5. Significant negative correlation between adiponectin and lumbar Z score

DISCUSSION

One factor correlated positively to bone mineral density is body weight. This can be explained by the mass effect, gravitational stress stimulating bone formation (3). Not completely elucidated is the relative importance of various body compartments, which may influence bone acquisition by mechanisms other than mechanical stress. Body weight is the sum of lean mass to fat mass. Increased muscle mass, combined with physical exercise, may contribute to a higher bone mass at young ages (4). Muscle mass is dependent not only on physical activity but also on hormones that have a direct effect on bone, such as IGF1 and testosterone (5). We demonstrated that IGF1 level positively correlates with bone mass (fig. 4), thus partially explaining the correlation between lean mass (source of IGF1 synthesis) of and bone mass. Low IGF1level is considered by other authors to be predictive of low bone mass and osteoporosis (6).

Adipocyte secretes specific peptide hormones, called adipocitokine (7). Leptin is considered to be a mediator between adipocytes and bone metabolism. Osteoblasts have leptin receptors, which stimulate bone formation through a direct mechanism, but inhibit the recruitment of osteoclast precursors, reducing osteolysis (8). However, by central effect, leptin stimulates the sympathetic nervous system leading to bone demineralization. The literature on the role of leptin on bone are conflicting, some authors describing a positive predictive role, while others suggest either the loss of leptin influence on bone when normalized in adipose tissue, or a negative predictive role in some populations (9, 10). In vitro and on animal models, adiponectin

seems to have direct effects mediated by receptors located on osteoblast, determining an increased bone turnover with predominance of osteoclast activity, possibly associated to bone mass loss (11). The effects observed in vitro and on animal models have been confirmed by some studies (12). In agreement with these studies, we found a negative correlation of adiponectin with bone mass.

CONCLUSIONS

We have demonstrated that the various body compartments influence bone mass acquisition in different ways, mass effect-independent mechanisms included. Thus, lean tissue mass has a more important predictive role on bone mass than fat tissue mass or total body weight. This effect could be explained by a hormonal profile favoring muscle development and collagen matrix, such as higher levels of IGF1.

Adipokine secretion profile has a buffer effect, adiponectin being a negative predictor of bone mass acquisition.

Maintaining aceptable bone mass in postmenopausal women is essentially influenced by premenopausal bone mass acquisition, which depends on weight, lean mass, estrogen impregnation, and IGF1 levels as positive factors, but also on adiponectin as possible adverse prognostic factor.

ATITUDINE TERAPEUTICĂ ÎN CAZ DE REACȚIE ALERGICĂ LA MEDICAȚIA ANTITUBERCULOASĂ. PREZENTARE DE CAZ

THERAPEUTIC ATTITUDE IN CASE OF ALLERGIC REACTION TO ANTITUBERCULOSIS MEDICATION – A CASE REPORT (Abstract). Medication used to treat tuberculosis is responsible for numerous side effects that have a major impact on patient's health, with a negative influence on the quality of life. Patients of all ages must be trained in order to recognize all the adverse effects and the undesirable reactions produced by antituberculosis medication. We report the case of a 24-year-old woman with generalized psoriasis and psoriatic arthropathy who was treated against tuberculosis. After 7 days of treatment with isoniazid, rifampicin, ethambutol and pyrazinamid she had severe allergic reaction with generalized pruritus and rash which were difficult to control with antiallergic treatment. Conclusions: Particular to this case is the absence in patient's history of the allergic reactions to medication. The re-establishment of treatment of tuberculosis was done by clinical trials and the patient had responded to only three drugs: isoniazid, rifampicin and ofloxacin, so the patient received an individual treatment due to adverse reactions to tuberculosis medications.
Key words: ALLERGIC REACTIONS, ANTITUBERCULOSIS MEDICATION, BACTERIOLOGICAL TEST

Tuberculoza rămâne o problemă de sănătate publică în România, dar şi pe plan mondial. Tuberculoza este o maladie infecțioasă, socială, asociată cu sărăcia şi malnutriția. Se estimează că în România sunt aproximativ 30.000 de bolnavi în toată țara (1).

Pacienții diagnosticați cu tuberculoză pulmonară sau extrapulmonară beneficiază de medicație antituberculoasă gratuită prin Programul Național de Control al Tuberculozei (PNCT). Tratamentul şi monitorizarea rezultatelor terapeutice sunt disponibile în studiile publicate şi documentația OMS (2, 3, 4, 5, 6).

Inițierea terapiei antituberculoase se face în spital sub directa observare a medicului pneumolog. Înainte de începerea oricărui tratament sau de reluarea unui tratament este necesar un examen clinic complet şi dozarea enzimelor hepatice, bilirubinei, creatininei, ureei, efectuarea unei hemograme. La pacienții cu vârstă peste 50 ani este recomandabil să se facă şi un examen oftalmologic (dacă se intenționează folosirea Etambutolului) precum şi o audiogramă (în cazul folosirii aminoglicozidelor sau a antibioticelor peptidice).

Pacienții de toate vârstele trebuie instruiți pentru a putea recunoaşte şi semnala efectele adverse şi reacțiile nedorite produse

de medicamentele anti-tuberculoase. Dacă apar simptome ce evocă toxicitatea medicației antituberculoase vor fi recomandate examene de laborator pentru a le identifica, iar conduita terapeutică va fi modificată corespunzător (7). Indiferent de schemele de tratament abordate de medicul pneumolog, medicația antituberculoasă este responsabilă de numeroase reacții adverse (8, 9).

PREZENTAREA CAZULUI

O pacientă de 24 ani, din mediu rural s-a internat în Clinica de Pneumologie Iași în aprilie 2011 cu diagnosticul de hemoptizie, observație tuberculoză pulmonară dreaptă, caz nou. De aproximativ o lună și jumătate pacienta prezenta inapetență, episoade infecțioase respiratorii recurente.

Din antecedentele personale patologice s-a remarcat diagnosticarea în decembrie 2010 cu psoriazis vulgar generalizat și artropatie psoriazică pentru care a urmat tratament cu Leflunomid 100 mg/zi apoi 20 mg/zi, ulterior cu Metotrexat 7,5 mg/săptămână și topic cu un derivat cortizonic, Hidrocortizon unguent cu o evoluție parțial favorabilă. Anterior internării în Clinica de Pneumologie pacienta a fost internată în Clinica de Dermatologie unde în urma unei radiografii pulmonare s-a decelat o opacitate în câmpul pulmonar mediu drept.

Examenul clinic a relevat la nivelul tegumentelor placarde eritematoase cu scuame toraco-abdominale, stare generală relativ bună, afebrilă cu absența sindromului inflamator, TA 100/60 mm Hg. Datele de laborator au arătat valori în limite normale ale funcției hepatice, renale, hematopoietice.

Radiografia pulmonară pune în evidență prezența unei opacități infiltrative cu hipertransparență centrală în câmpul pulmonar mediu drept, nodul pulmonar LID.

La examenul bacteriologic repetat de spută BK a fost negativ. S-a efectuat examen fibrobronhoscopic: fără modificări la examinarea arborelui bronșic bilateral, s-a prelevat aspirat bronșic pentru BK. La examenul bacteriologic de aspirat bronșic BK a fost negativ. Spirometrie în limite normale. De asemenea se face testarea la Quantiferon TB GOLD, iar rezultatul a fost pozitiv.

Datele obținute clinic și paraclinic au pus în discuție inițierea tratamentului antituberculos categoria I de tratament: Izoniazidă (HIN), Rifampicină (RIF), Etambutol (EMB) și Pirazinamidă (PZM) . Tratamentul este tolerat bine, pacienta prezintă stare generală bună fără reacții alergice la medicația antituberculoasă. După 7 zile de tratament apare o reacție alergică severă cu prurit și eritem generalizat, se decide întreruperea tratamentului antituberculos. Se reîncepe testarea separată a tuberculostaticelor, dar pacienta prezintă reacție adversă severă cutanată la: HIN, RIF, PZM fără a se mai încerca testarea și la EMB. Reacția adversă cedează cu dificultate la medicația antialergică. Medicul curant a completat fișa pentru raportarea spontană a reacțiilor adverse la medicamente în cazul de față la medicația antituberculoasă și a fost trimisă la Agenția Națională a Medicamentului. După o perioadă de aproximativ 2 luni timp în care pacienta este urmărită clinic, paraclinic și radiologic pacienta primește tratament pentru psoriazis cu o evoluție foarte bună a acestuia se decide intervenția chirurgicală cu excizia formațiunii în vederea unui diagnostic de certitudine. După întreruperea oricărei terapii pacienta se internează în Clinica de Chirurgie toracică cu diagnosticul de tuberculom lob inferior drept și se va interveni chirurgical pentru lobectomie inferioară dreaptă, drenaj pleural. Fragmentul pulmonar se trimite la laboratorul de bacteriologie și se confirmă BK pozitiv în piesa operatorie.

Se decide reînceperea tratamentului antituberculos cu Ofloxacină 300 mg/zi, Rifampicină 150 mg/zi, tolerează, a doua zi se

creşte doza la 300 mg/zi, tolerează, a treia zi se creşte doza la 450 mg/zi. În ziua a patra se introduce Etambutol 400 mg/zi, după 3 ore pacienta acuză prurit la nivelul feței dorsale a mâinii drepte şi la nivel toraco-abdominal, eritem diseminat pe abdomen şi torace prezența de micropapule la nivelul membrelor superioare. Se administrează medicație antialergică şi se opreşte administrarea Etambutolului. După două zile se introduce Izoniazidă 100 mg/zi, pacienta tolerează medicația, se creşte treptat doza la 250 mg/zi. Starea generală a pacientei este bună suportă bine tratamentul individualizat, pacienta se externează pentru continuarea terapiei antituberculoase la domiciliu.

DISCUȚII

Raportat la numărul total de pacienți internați şi tratați cu medicație antituberculoasă în Spitalul Clinic de Pneumologie Iaşi în perioada 2007-2011 incidența reacțiilor adverse este următoarea pe ani (1,46% / 2007, 2,97% / 2008, 2,17% / 2009, 3% / 2010 şi 3% / 2011). Numărul de pacienți tratați cu medicație antituberculoasă a scăzut semnificativ în anul 2010 şi 2011, în schimb incidența reacțiilor adverse este sensibil mai mare în aceşti ani. Cele mai multe reacții adverse s-au semnalat la un singur medicament Pirazinamida 500 mg (75,6%), în timp ce (24,4%) reprezintă reacțiile adverse semnalate la mai multe medicamente din schemele de tratament. În ce priveşte repartiția pe sexe a fost mai crescută la sexul masculin (88,8%) comparativ cu cel feminin, grupa de vârstă cea mai afectată fiind 45-54 ani, preponderent din mediul rural.

CONCLUZII

Particularitatea cazului prezentat constă în faptul că pacienta nu a mai avut episoade de reacții alergice la medicamente. Datorită reacțiilor adverse severe la Pirazinamidă şi Etambutol va beneficia de tratament individualizat format din: Izoniazidă 250 mg/zi, Rifampicină 450 mg/zi şi Ofloxacin 300 mg/zi.

INCIDENTAL DISCOVERY OF HUMAN TRICHINELLOSIS ASSOCIATED WITH ORAL SQUAMOUS CELL CARCINOMA. CASE REPORT (Abstract): Trichinellosis is a parasitic infestation that is caused by roundworms of the Trichinella type and which affects the skeletal muscles. In most parts of the world there have been reports of trichinellosis in humans, with a lower incidence in countries in which pork is not traditionally eaten, such as India. This article reports a rare case of an incidental finding during a reconstructive surgery procedure on a 67-year-old man suffering from squamous cell carcinoma of the floor of the mouth. The intervention helped prevent long-term morbidity caused by trichinellosis in our patient. The case was successfully resolved by our reconstructive surgery followed by antiparasitic medication. We also discuss the pathogenesis and carcinogenic potential of trichinellosis, suggesting the critical importance of timely diagnosis and treatment of this infestation. **Keywords**: ORAL CANCER, PARASITOSIS, MIOCUTANEOUS FLAP, TRICHINELLA SPIRALIS, TRICHINELLOSIS.

Trichinellosis is caused by helminth (roundworms) of the species *Trichinella*. It is spread by the consumption of undercooked or raw meat products, infested by encysted larvae (1). Most often the meat is pork or wild boar but can also come from other species such as bears or dogs, depending on culinary customs (2). During the initial phase of the infestation the larvae are released from their cysts and begin to invade the wall of the small intestine, where they develop into adults and can cause digestive symptomatology such as abdominal pain, vomiting, diarrhea, or even unspecific systemic signs such as rashes, fatigue, fever, arthralgia, myalgia (3). After about one week, the females release new larvae that begin to migrate using the capillaries towards various organs such as the lymph nodes, myocardium, retina, however only larvae that reach the skeletal muscles survive and begin to affect these cells,

causing fever, muscle pains and rash (4).

The presenting complaints most commonly include myalgia, fever, rash and fatigue (5). Some cases may be completely asymptomatic, however complications have been described, such as myocarditis, central nervous system damage or pulmonary damage. In rare cases there is neurologic damage such as respiratory paralysis, ataxia, or even cerebral venous sinus thrombosis from contamination of the central nervous system (6). Pyomyositis is a rare complication by primary infection of the skeletal muscle, usually caused by Staphylococcus aureus, and is endemic in tropical areas (7). In most cases, the diagnosis is based on symptoms and confirmed by specific antibodies in the blood or by tissue biopsy.

Once diagnosed, the infection can be treated with mebendazole, albendazole or other antiparasitic medication, rapid treatment neutralizing the parasites and preventing further deterioration of the symptoms (8). Early administration of anthelmintic drugs decreases the likelihood of larval encystation, especially if administered within the first days after contact (9). However, most cases are diagnosed much later, when the symptomatology is significant (10). If left untreated, the infected humans represent a dead-end host, and the parasite remains in a cystic stage for the rest of the host's life.

CASE REPORT

A 67-year-old man was referred to the Oral and Maxillofacial Surgery Clinic of the „Sf. Spiridon" Emergency Hospital, Iasi, Romania with the suspicion of squamous cell carcinoma of the floor of the mouth. The patient had a medical history of hypertension, atrial fibrillation, varicose veins in the lower extremities and total bimaxillary edentation. His treatment included Acenocumarol, Digoxin, Carvedilol, Spironolactone, and Perindopril-Amlodipine. He resided in a rural area of Romania and was retired. The patient was a smoker for about 50 years (roughly 10 cigarettes per day) and an occasional alcohol consumer. Occasionally, he enjoyed eating undercooked pork or boar. The patient declared that he initially noticed the oral tumor in early 2017 and that at first it was not painful, becoming more and more uncomfortable as the tumor started to grow.

Extraoral physical examination identified only a right submandibular lymphadenopathy. Intraoral examination revealed normally colored vestibule and tongue, with a mid-sized palate and no invasion of the superior and inferior vestibule. We identified a neoplastic mass of the floor of the mouth extending to the anterior third of the tongue, ulcerated, hardened and painful both spontaneously and upon contact. Tongue with normal tonus and reduced mobility due to the fixation to the floor of the mouth in the anterior region.

Orthopantomography revealed an area of radio transparency circumscribing 33, poorly delimitated. Thoracic X ray revealed signs of aortic atherosclerosis and otherwise normal pulmonary areas.

Cardiology exam revealed signs of digitalis toxicity on EKG, subsequently Digoxin was stopped. Acenocumarol was stopped and replaced with Clexane twice a day. Echocardiography revealed mitral annular calcification and thickening of the tricuspid and aortic valves, mild bilateral atrial dilation and mild aortic atherosclerosis, with an ejection fraction of 55%.

The hematological exam was largely normal, except for an increased MCV of 101.3/fL and slight elevation of monocyte percentage to 13.3%.

During hospital stay the patient presented an allergic reaction characterized by acute

urticaria of probable food cause and corticoid and antihistaminic treatment was initiated.

A decision was taken to perform a bilateral radical neck dissection followed by the excision of the tumor with adequate safety margins, followed by immediate reconstruction with pedicelled pectoralis major myocutaneous flap, a versatile flap with an excellent reach to face oral cavity and neck region (11). Upon inspection of the muscular fibers we noticed a peculiar aspect of skeletal muscle fibers in the thoracic, head and neck areas, suggestive of cystic, parasitic lesions, (fig.1) prompting the decision to send a small fragment of the pectoralis minor for extemporaneous anatomopathological examination (fig.2). The results showed skeletal muscle fibers containing cystic elements, outlined by a connective tissue and containing spiraled parasitic organs belonging to a possible nematode, highly suggestive of *Trichinella spiralis* infestation. After discussion with the pathologist we decided to send another muscle biopsy sample from the platysma muscle to obtain hematoxylin and eosin-stained (H&E) sections from the paraffin wax-embedded sample to better identify the parasitic nematode. The sections were examined by a clinical biologist from the Iasi Infectious Hospital confirming the cystic stage of a *Trichinella spiralis* infestation.

Hematoxylin and eosin-stained (H&E) sections from paraffin wax-embedded muscle revealed skeletal muscle fibers containing cystic elements, outlined by connective tissue and containing spiraled parasitic organs identified as *Trichinella spiralis* (fig.2-3). Masson's trichrome stain on paraffin-embedded sections showed the cystic stage of a *Trichinella spiralis* nematode surrounded by muscle fibers and connective tissue highlighted in a bright blue color (fig.4-5). The patient was discharged after receiving a full treatment with Mebendazole 400 mg three times a day for 10 days, supportive drugs and is being followed up regularly without complaints (12).

DISCUSSION

Trichinella infestation has been reported in association with carcinomas of oral cavity and breast (13). The nematodes seem to target the oxygenated skeletal muscles (14). In typical cases the larvae can be seen encased in a cyst wall composed of the host tissue, with lymphocytic and eosinophilic infiltrate, producing a characteristic appearance in biopsy samples that provides a diagnostic (15).

Bruschi (16) showed the cytotoxic role of eosinophils *in vitro*, in human antibody dependent cellular cytotoxic reactions that can be attributed to interleukin-5 produced by the Th2 subset of CD4+ T cells. The coexistence of trichinosis infestation and tumor tissues has been previously observed in other reports such as that by Jozo Kristek (17). It remains to be proven if trichinosis is a carcinogen involved in the development of malignancies of the oral cavity, constant irritation by the parasitic cysts may be responsible for the upregulation of VEGF and other modifications of external kinases (18).

Ever since the discovery of the antitumor effect of *Trichinella spiralis* in the 1970s many research teams have proved with relative success that *Trichinella spiralis* possesses antitumor activities. Unfortunately, the research has proved to be inconsistent with little advancement in the field over the past years. Consequently, the underlying mechanisms explaining the inhibitory effects remain unclear, and there have been no clinical trials that provide adequate evidence in support of a signifi-

cant effect of *Trichinella spiralis* over the prevention or treatment of cancers (19). Meanwhile, some other researches also suggested that *Trichinella spiralis* may cause or contribute to coinfection with a tumor (20).

The presented case represents an incidental discovery of a *Trichinella spiralis* infestation and as such it cannot be confirmed or ruled out as a cause of the squamous cell carcinoma that prompted the need for surgery, but recent research shows that coinfection is a possible cause for the development of cancers (18-22). The presence of the cystic parasites in the muscular fibers represents a constant local inflammation source that can be responsible for the appearance of a neoplastic process. The cystic nematode remains surrounded by connective tissue causing little disturbance to the systemic biochemistry and hematologic tests, in many cases the infestation can remain undetected for years. The incidental discovery of the parasitic infestation represents a unique opportunity because it allowed us to perform an adequate examination and provide treatment.

CONCLUSIONS

We report a case of asymptomatic *Trichinella spiralis* infestation, diagnosed incidentally while the patient underwent surgery for oral squamous cell carcinoma. To our knowledge this is the first case reported in our geographical area. Our findings come to support and lend credibility to the claims of carcinogenic potential, considering the presence of this parasite in other case reports associated with cancers in general and specifically with oral cancers. We believe further research is warranted to verify this claim with a larger cohort. The fortuitous discovery of the parasitic infestation represents a rare opportunity to perform adequate pathological examinations to document the cystic stage of infestation in humans, rarely seen today due to the invasive nature of muscle biopsies and the possibility to identify the parasite using hematological tests.

LETHAL HYPOTHERMIA-THE IMPORTANCE OF POSTMORTEM CONCENTRATION OF ENDOCAN

Endocan is an endothelial cell-associated proteoglycan expressed and secreted by vascular endothelial cells of various organs, preferentially by the lung in response of pro-inflammatory cytokines. This molecule is known to be a good biomarker for multi-organ failure and endothelial dysfunction especially in cases of sepsis, severe sepsis and septic shock. In a study, endocan values were determined in three biological samples (femoral serum, vitreous humor and urine) and three different group cases (hypothermia, sepsis, non-hypothermia/ non-sepsis cases), with a total amount of 76 autopsy cases prospectively selected by several inclusion criteria. The results of the study indicate that generalized inflammation and endothelial activation with increased endocan concentration in autopsy collected biological samples it is not a characteristic of hypothermia fatalities following cold exposure. The limitations of the study are linked by the small number of autopsy cases, precised selection criteria and, being a prospective study, much more cases would be needed to confirm the findings (E. Descloux *et al.* Endocan concentrations in postmortem serum, vitreous humor and urine in victims of lethal hypothermia. *Journal of Forensic and Legal Medicine* 2017; 50: 39-43).

COLON CAPSULE ENDOSCOPY COMPARED TO COLONOSCOPY FOR COLORECTAL NEOPLASMS DIAGNOSIS: AN INITIAL EXPERIENCE AND A BRIEF REVIEW OF THE LITERATURE (Abstract): Conventional colonoscopy is regarded as the gold standard procedure for the diagnosis of colorectal neoplasms despite its several limitations including invasiveness, discomfort and potential complications. Colon capsule endoscopy (CCE) could be an attractive alternative method to the invasive colonoscopy for the diagnosis of colorectal cancer and polyps. Publications regarding the use of CCE for detecting colorectal cancer and polyps, as well as our experience, were reviewed. The new second-generation CCE (PillCam COLON 2) has improved accuracy compared with the first-generation system for detecting colorectal neoplasms. **Key words**: COLON CAPSULE ENDOSCOPY, COLONOSCOPY, COLORECTAL POLYPS.

Colorectal cancer (CRC) is a leading cause of morbidity and mortality worldwide. Approximately 90% of CRC develop from benign adenomatous polyps, and current guidelines recommend screening colonoscopy with subsequent polypectomy to prevent progression into cancer (1). With such screening program in the United States, a decrease in incidence and mortality of CRC was reported (2, 3). However, colonoscopy has several limitations including invasiveness, discomfort, embarrassment, high cost, sedation, and potential complications. Therefore, many patients are reluctant to undergo this procedure, and generally, participation in colonoscopy screening is unacceptable low (4).

Colon capsule endoscopy (CCE) is a new, safe non-invasive and patient-friendly procedure for visualizing the colon with no need of sedation, intubation, air insufflation or radiation; this new technology might become an alternative method to the invasive conventional colonoscopy in CCR screening and polyp detection.

In this paper we aim to present our personal experience with CCE, to summarize the recent impressive technical achievements, and to review the most recent studies addressed to this subject.

COLON CAPSULE ENDOSCOPY: DEVICE DESCRIPTION

The PillCam Colon capsule 1 (PCC1)

endoscope (Given Imaging Ltd., Yoqneam, Israel) measures 11 x 31 mm and has two cameras that enables the device to acquire video images from both ends with a frame rate of 4 images per second, and a total operation duration of about 10 hours (5). After an initial few minutes of image transmission, the capsule enters a delay mode of approximately two hours, after which (when capsule is probably in terminal ileum) it "wakes up" and restarts the transmission of video images. The recorded data are downloaded into the Given Imaging RAPID workstation for review of the colon video.

The PillCam Colon 2 (PCC2) (Fig. 1) – the second generation capsule endoscopy system – measures 11.6 x 31.5 mm, and the angle of view has been increased to 172 degrees for each camera (from 154° in PCC1), offering a panoramic view. The new Data Recorder 3 is a "thinking" recorder which controls the capsule image rate in real time (4 images per second when the capsule is stationary and 35 images per second when it is moving) as opposite to the fixed rate of 4 images per second of PCC1; this technical improvement conserves battery energy (5). The Data Recorder 3 also recognizes location of the capsule (stomach, small intestine) and how long it has been there, thus assisting medical staff and patient through the procedure (administration of a prokinetic or laxative). The new RAPID software includes a graphic interface tool for polyp size estimation in millimeters.

Fig. 1. PillCam Colon 2 and Data Recorder 3

COLON PREPARATION

The bowel preparation procedure is similar to that used for conventional colonoscopy. However, it is more rigourous since no suction of liquid remnants is possible during capsule endoscopy, unlike during colonoscopy. Briefly, it consists of clear liquid diet on the day before capsule ingestion and 3 liters of polyethyleneglycol (PEG) ingested in the evening before procedure; another liter of PEG is ingested in the next morning, then the capsule is swallowed with a glass of water (6). One or two "boosters" (sodium phosphate) are administered after 1-2 hours if the capsule has entered the small bowel, followed by a

laxative (bisacodyl suppository) if the capsule has not been excreted (6, 7). The reason for the "vigorous" bowel preparation is to maintain the colon cleanliness and to promote the capsule progression through the gastrointestinal tract.

CONTRAINDICATIONS

CCE should not be performed in patients with dysphagia, known or suspected bowel obstruction, surgical anastomosis, diverticulosis, cardiac pacemaker or other implanted electromedical devices, pregnant female patients, known allergy to PEG, sodium phosphate or bisacodyl.

COMPARISON OF COLON CAPSULE ENDOSCOPY WITH CONVENTIONAL COLONOSCOPY

Several studies have been performed with the first-generation colon capsule endoscopy (PCC1) which showed promising accuracy compared with conventional colonoscopy for detection of colorectal significant lesions (8-13).

We have analyzed the first results with PCC1 at our institution in patients with or without personal or family history of CRC or polyps and compared them with those obtained at colonoscopy. Patients included were 17 men and 11 women, aged 26 to 74 years (mean age: 56 $\pm$ 12 years) who underwent both capsule and colonoscopy examinations at the Iasi Institute of Gastroenterology and Hepatology between May 2008 – December 2010. Colon preparation with PEG was similar for capsule endoscopy and colonoscopy. All CCE recordings were read by the same physician, and all colonoscopies were performed by two experienced endoscopists. For statistical analysis, colonoscopy was considered the gold standard, and per-patient comparisons were made as in other studies. No CRC were detected by CCE and colonoscopy, but colorectal polyps were found in 9 (32.1%) patients by colonoscopy and in 7 (25%) patients by CCE, the agreement between these two examinations being significant (p =0.19) (Fig. 2).

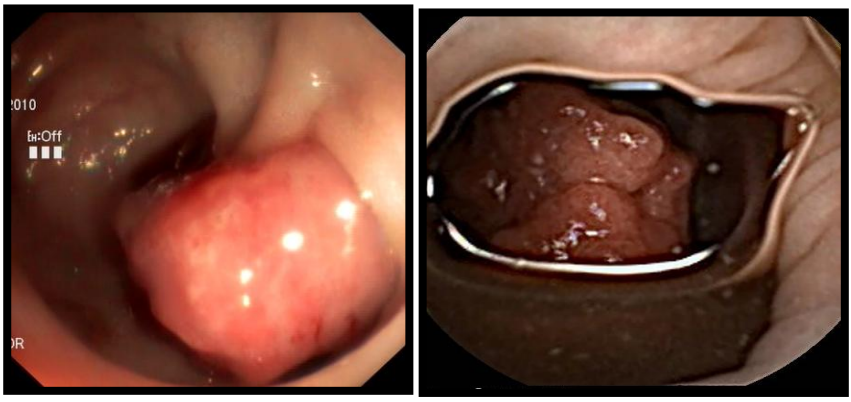

Fig. 2 a, b. Colonic polyp seen at colonoscopy (a) and colon capsule endoscopy (b)

The sensitivity and specificity of CCE for the detection of colorectal polyps (any size) were 73.5% and 81.2%, respectively. The positive predictive value of CCE was 69.8% and the negative predictive value was 83.1%. The tolerance of CCE procedure was excellent, and no complications were reported.

Colon capsule endoscopy was compared to conventional colonoscopy for the detection of colorectal polyps and cancer in several studies (7-17). Van Gossum et al (14) in a prospective, multi-center study found that sensitivity of CCE for detecting colonic polyps, advanced adenomas, and colorectal cancer was relatively low in comparison with colonoscopy. A low sensitivity of CCE for detection of relevant colorectal polyps was also reported in another recent published study (15). Sacher-Huvelin et al (16) in a prospective, multi-center trial to compare CCE (first generation of colon capsule) and colonoscopy in asymptomatic subjects enrolled in screening or surveillance programmes for the detection of colorectal neoplasia, have found that CCE cannot replace colonoscopy as a first-line investigation for screening and surveillance of patients at risk of cancer. On the other hand, several studies have reported that CCE was effective in detecting colorectal polyps. Thus, Devière at al (13) in a multi-center European study of detecting colon cancers and polyps using CCE (PillCam Colon 1) compared to conventional colonoscopy found encouraging accuracy of CCE for detecting polyps and suggested that this new method for visualizing the colon may be an alternative for patients who cannot or are unwilling to undergo colonoscopy. Gay et al (10) found CCE to be an effective method in detecting clinically relevant colonic findings in patients with an indication of conventional colonoscopy. Two recent meta-analyses (11, 12) reported CCE to be a reasonable method for screening asymptomatic subjects for colorectal polyps.

The most, if not all above mentioned studies were performed with the first generation of CCE. Recently, Eliakim et al (17) reported an improved accuracy of the second-generation CCE (PCC2) compared with the first-generation system (PCC1) in detecting colorectal polyps. Thus, the sensitivity to diagnose patients with colorectal polyps increased from 60% in the previous study with PCC1 (9) to 90% and the only reason for greater diagnostic yield was the technological improvements in the PCC2 system. Hassan et al (18) have evaluated the cost-effectiveness of CCE based on a Markov mathematical model and found the cost-effectiveness potentially superior to colonoscopy.

CONCLUSIONS

Colon capsule endoscopy is a safe, minimally invasive, very well accepted by patients, easy to perform procedure which with new technological improvement could become an option for the screening of colorectal polyps and cancer.

2. Clinica IV Medicală – Nefrologie

THE ROLE OF ULTRASONOGRAPHY EXAM IN ORBITAL-OCULAR TUMORS (Abstract): Ophthalmology is one of the specialties that have particularly benefited from the contribution of ultrasonography exam as a method of investigation. Ultrasonography is very much essential for diagnostic to complement other clinical and laboratory investigations, providing images in real time. The basic principle of diagnostic ultrasound is to study and to interpret the changes they undergo when crossing ultrasonic waves diverse biological properties different sound, and such injuries can be traced in the dynamics or can be documented on photographic paper and thus can diagnose correct certain eye diseases. The indications for performing ultrasound consist in: measurement of distances and volumes, examine difficult or inaccessible case of opaque media; ophthalmoscopic view of a mass lesion, examine the orbit or optic nerve. The advantages of ultrasound for orbital-ocular tumors are represented by the fact that ultrasound is a noninvasive method, safe, well tolerated, less expensive that the advantage of determining the position and distance from structures ocular tumor. High frequency ultrasound provides excellent resolution of 0-1 to 0.01 mm, and serial scans allow tracking progress and measuring lesion diameters tumor while allowing monitoring and evaluation of stereotactic radiation treatments applied to small tumors. In conclusion ultrasound allows not only early diagnosis of eye tumors, but accurate assessment of the proposed therapy and of the evolution of detected mass lesions or tumors. **Key words**: ULTRASONOGRAPHY EXAM, ORBITAL EXAM, OCULAR TUMORS, OUTCOME.

Ultrasunetul este un fenomen de undă şi se încadrează în categoria oscilațiilor şi undelor mecanice, constituind o parte a acusticii. Ultrasonografia este o metodă de investigație paraclinică (imagistică) bazată pe principiul emiterii undelor sonice la țesuturi şi al recepționării şi interpretării undelor reflectate. Oftalmologia este una dintre specialitațile care au beneficiat în mod deosebit de aportul ecografiei ca modalitate de investigație, examenul ecografic fiind de foarte multe indispensabil în scop diagnostic pentru complementarea celorlalte investigații clinice şi paraclinice, furnizând imagini în timp real.

Indicațiile efectuării examenului ecografic în oftalmologie sunt (1): **1.** măsurarea unor distanțe sau volume (biometrie,

grosime corneeană); **2.** examinarea dificilă sau inaccesibilă în caz de medii opace (cataractă, leucom corneean); **3.** vizualizarea oftalmoscopică a unei leziuni de masă retinocoroidiene; **4.** depistarea eventualelor leziuni posttraumatice şi urmărirea evoluției acestora în timp (hifemă, detaşarea corpului ciliar, recesia unghiului irido-corneean, decolarea de retină); **5.** examinarea orbitei sau a nervului optic; **6.** documentarea evoluției tumorilor oculare în timpul tratamentelor de iradiere (2).

Modalități de producere a ultrasunetelor cu aplicabilitate în oftalmologie

În oftalmologie sunt folosite unde cu frecvență cuprinse între 10-50mHhz. Ultrasunetele sunt generate şi emise de un transductor piezoelectric cu un cristal de cuarț situat în interiorul sondei exploratoare; emisia este discontinuă, astfel încât transductorul este şi emițător şi receptor al ecourilor ultrasonice. Ultrasunetele reflectate sunt recaptate de sondă şi sunt transformate în semnal electric care este amplificat şi vizualizat pe monitorul ecografului. Leziunile pot fi urmărite în dinamică sau documentate pe hârtie fotografică (3). Se folosesc: **1.** modul A scan biometry – pentru măsurători axiale ale globului ocular; **2.** UBM – ultrabiomicroscopie sau VHFU (very high frequency ultrasound – ultrasunete de înaltă frecvență) pentru examinarea polului anterior; **3.** modul B-scan cu/fără A scan vector, cu/fără display tridimesional; **4.** modul B-scan şi A-scan standardizat; **5.** modul 3D tridimensional (modul C) – tehnică prin care se obține reconstrucția statică şi procesarea tridimensională a imaginii după stocarea multiplelor secțiuni obținute prin modul B; **6.** modul Doppler color pentru vizualizarea neoformațiilor vasculare şi a şunturilor arterio-venoase; **7.** Doppler în undă continuă; **8.** Doppler pulsatil (4).

Ecografia modul A (amplitudine) – este emis un fascicul subțire de unde paralele ce traversează ochiul şi scanează un ax mic de țesut. Se analizează: **1.** distanța de la sondă la structura examinată (biometrie); **2.** amplitudinea ecoului (înălțimea spiculilor) care depinde de natura interfeței reflectante (ecografie cantitativă). Ecograma A normală (fig. 1) cu sonda aplicată pe cornee prezintă: **1.** ecou înalt dat de cornee; **2.** linie izoelectrică corespunzătoare UA din CA; **3.** două ecouri înalte (egale) date de capsula anterioară şi posterioară a cristalinului; **4.** linie izoelectrică lungă corespunzătoare vitrosului; **5.** ecou înalt generat de peretele posterior al globului ocular; **6.** ecouri descrescătoare corespunzătoare țesutului retroocular.

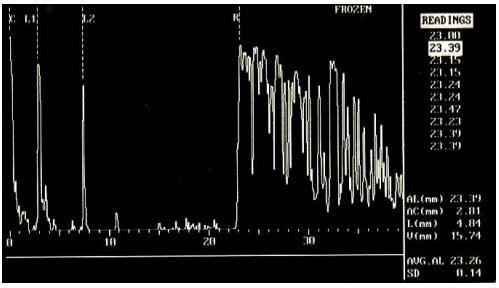

Fig. 1. Ecogramă modul A normală (axial orizontal)

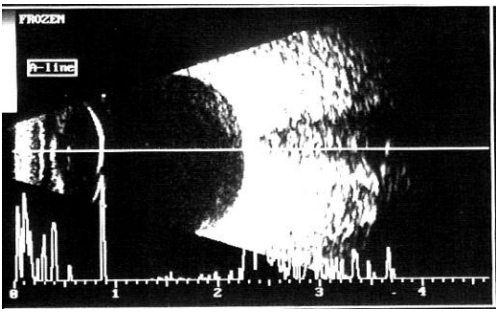

Fig. 2. Ecogramă modul B normală (axial orizontal)

Ecografia modul B – este emis un fascicul de unde oscilant ce traversează ochiul şi analizează o felie de țesut. Ecograma B

normală (fig. 2) prezintă: **1.** zonă ecogenă inițială dată de cornee; **2.** zonă ecotransparentă corespunzătoare umorului apos; **3.** două ecouri ecogene, convex-concav, subțiri date de cele două capsule cristaliniene, între care se observă o zonă ecotransparență (cristalinul); **4.** zonă ecotransparentă (vitrosul); **5.** ecou hiperecogen concav generat de peretele scleral posterior; **6.** ecouri corespunzătoare grăsimii retrooculare (5).

Examinarea globului ocular – Globul ocular se examinează de la nivelul polului posterior spre periferie, evaluând fiecare cadran prin scanare atentă cu sonda de la limbul sclerocorneean spre fornixul conjunctival. Pacientul stă întins sau în şezut cu capul sprijinit pe tetiera scaunului şi cu privirea orientată spre tavan, se aplică anestezic corneean topic; copiii pot fi examinați cu anestezie generală sau sub sedare uşoară. Capătul sondei (oval sau rotund) se aplică în contact cu corneea (după anestezie) prin intermediul unei fine pelicule de gel si se scanează în toate cadranele urmărind integritatea structurilor oculare.

TABELUL I

Metodologia şi folosirea ecografiei oculare (după Atta HR 1996) (6)

Informații	Modul ecografic
Leziuni detectate	
Examinare topografică	
Forma	B-scan
Localizare	B-scan
Extindere	B-scan

Structură internă (regularitatea amplitudinii ecourilor şi a intervalului acestora de succesiune)	A-scan
Atenuare sonică (datorată absorbției ultrasunetelor la trecerea prin țesuturi)	A-scan
Examinare kinetică	
Mobilitate	B-scan
Mobilitate după mişcarea globului ocular	A şi B-scan
Vascularizație	A-scan

Se fac *6 scanări obligatorii*: **1.** Axial – cristalinul şi capul nervului optic sunt plasate în centrul ecogramei: **a.** orizontal cu proba perpendiculară pe axul central al corneei, markerul de pe lateralul sondei nazal (ora 3 pentru OD şi ora 9 la OS) – pentru scanarea polului posterior; **b.** axial vertical – marker la ora 12; **2.** Transversal 12-6 (sonda la ora 12 scanează regiunea orei 6); **3.** Transversal 6-12 (sonda la ora 6 scanează regiunea orei 12); **4.** Transversal 9-3 (sonda la ora 9 scanează regiunea orei 3); **5.** Transversal 3-9 (sonda la ora 3 scanează regiunea orei 9); **6.** Longitudinal 3-9 pentru OD şi 9-3 pentru OS pentru evaluarea regiunii maculare. Există 4 grupe mari de aspecte topografice anormale: opacitățile membranoase, leziunile de masă tumorală, opacități vitreene (unice/multiple), anomalii de contur ale globului ocular. *Examinarea cinetică* (în dinamică) a structurilor normale şi anormale este foarte importantă şi evidențiază: **1.** mobilitatea țesuturilor analizate simultan cu mişcarea globului ocular; **2.** vascularizația intratumorală decelabilă prin modul A – vibrații fine şi rapide verticale în interiorul ecoului tumoral (7). *Examinarea orbitei* – este o investigație utilă în patologia orbitei care permite localizarea topografică a leziunilor orbitare anterioare. În cazul leziunilor orbitare, CT şi RMN sunt superioare ca metode de diagnostic ecografiei. Ecografia de orbită este indicată în: **1.** exoftalmie unilaterală şi deplasarea globului ocular; **2.** tulburări de motilitate oculară şi durere oculoorbitară; **3.** congestia oculară unilaterală şi creşterea PIO (fistula carotido-cavernoasă traumatică); **4.** edemul sau atrofia nervului optic asociat cu ocluzia venoasă; **5.** pliuri coroidiene (tumori intraconale, oftalmopatia tiroidiană severă); **6.** traumatismele orbitei (8). Examinarea ecografică a orbitei se începe tot cu modul B pentru stabilirea

formei şi topografiei leziunii. Urmează modul A pentru evaluarea reflectivităţii şi corelarea directă cu structura histologică. Se impune examinare bilaterală şi compararea imaginilor ecografice.

Calea transoculară se realizează prin plasarea transductorului direct pe globul ocular, în incidenţa transoculară axial orizontal cu planul de secţiune al nervului optic. Unghiul anterior al triunghiului dat de nervul optic este în general între 40-70° (dacă se măreşte poate indica lărgirea patologică a nervului optic sau a tecilor nervului optic). Dacă scanările se fac superior sau inferior de nervul optic, triunghiul hipoecogen determinat de nervul optic este absent, iar modelul retrobulbar apare ca o zonă uniformă albă. *Calea paraoculară* se realizează prin plasarea transductorului pe pleoapele închise, în spaţiul dintre glob şi marginea orbitei; se evidenţiază leziunile plasate anterior (tumori de glandă lacrimală, mucocel, chist dermoid). *Examenul ecografic în cazul tumorilor intraoculare (9)* – ecografia poate analiza tumori cu mărimi de peste 0,5mm, însă precizarea diagnosticului final se face numai prin corelarea datelor examenului clinic şi ecografic cu alte investigaţii, iar certitudinea aparţine examenului anatomopatologic.

Tumori coroidiene – *Melanomul malign de coroidă* (MMC) – tumoră melanocitară malignă, una dintre cele mai frecvente tumori maligne primare ale ochiului – 75%. Criterii de diagnostic ecografic în cazul MMC: *Modul A* – **1**. ecou iniţial intens reflectiv urmat de un grup de ecouri cu reflectivitate medie şi mică (reflectivitate internă 5-60% din ecoul scleral), bine individualizate, cu structură omogenă; **2.** vitrosul pare scurtat, coloană de ecouri descrescătoare, ecourile nu ajung la linia izoelectrică; **3.** oscilaţii spontane, rapide ale ecourilor verticale vascularizaţie intratumorală – semn specific în MMC; **4.** ecografia permite măsurarea biometrică a tumorii. *Modul B* – **1.** zonă ecogenă compactă, densă, relativ omogenă, bine conturată, cu aspect în dom (membrana Bruch este intactă) sau de ciupercă (tumora a perforat membrana Bruch) care proemină în aria de ultrasonotransparenţă a vitrosului; **2.** zonă cu reflectivitate scăzută la baza tumorii – excavaţia coroidiană care deprimă conturul peretelui scleral; **3.** umbra acustică – umbră orbitară din cauza absorbţiei mari a ultrasunetelor de către tumoră; **4.** unghiul kappa format de orizontala ce trece prin primul ecou intratumoral; **5.** tendinţă de creştere a leziunii la examinări repetate; **6.** DR secundară (fig.3). *Nev coroidian tumoră benignă melanocitară a coroidei* **(**fig. 4**) –** modul A: reflectivitate crescută 90-100%, spike cu platou. Modul B – mică elevaţie plată sau în dom care nu creşte la examenele ulterioare sau creşte foarte lent.

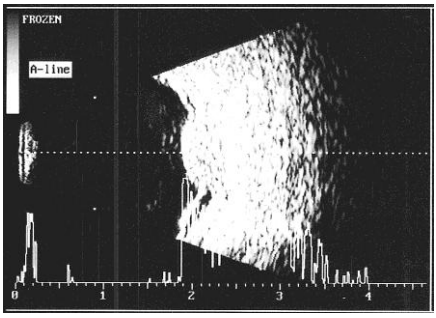

Fig. 3. MMC cu DR exsudativă secundară

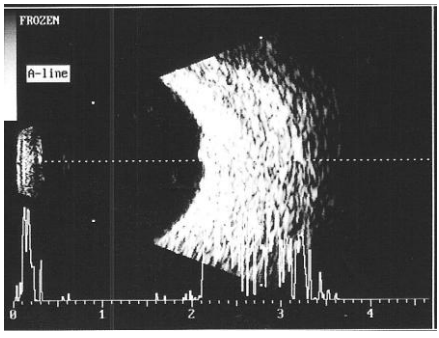

Fig. 4. Nev coroidian

Hemangiomul coroidian este un hamartom vascular congenital benign al coroidei. Modul A – structură internă regulată cu reflectivitate crescută şi atenuare sonică slabă. Ecografia cinetică demonstrează caracterul non vascular al afecţiunii. Modul B – proeminenţă ecogenă în dom sau îngroşare difuză a stratului retinocoroidian, localizată la nivelul polului posterior. Nu prezintă excavaţie coroidiană sau fenomenul de atenuare sonică la nivelul grăsimii retrooculare. *Tumori metastatice coroidiene* – modul B zonă ecogenă de tip infiltraţie cu una sau două proeminenţe şi cu bază tumorală întinsă, mai extinsă decât înălţimea tumorii; zona de predilecţie este la nivelul polului posterior. Modul A – ecouri interne neregulate cu amplitudine între 40-80%, înălţimea spikeului *tumorale creşte către scleră* (la MMC scade către scleră) (10). Atenuare sonică slabă.

Tumori retiniene – *retinoblastomul (RB) este un neoplasm primar malign al retinei, cea mai frecventă tumoră intraoculară la copii.* Pe ecografia în modul A şi B imaginea unui retinoblastom compact este similară unei tumori coroidiene, cu diferenţa că retinoblastoamele apar cu precădere retroecuatorial. Forma chistică este nesistematizată, pretând la confuzii cu hemoragia vitreană organizată şi fibroplazia retrolentală. *Foarte importantă este prezenţa calcificărilor intratumorale în cazul retinoblastomului care sunt hiperreflective pe ecograma B, foarte absorbante, lăsând un „con de umbră" posterior* (11). *Forma solidă* – o formaţiune tumorală intraoculară, hiperecogenă în aria de ultrasonotransparenţă a vitrosului. Prezenţa zonelor cu reflectivitate înaltă intratumorală reprezintă unul din criteriile importante de diagnostic (90-95% din cazuri). *Forma chistică* – o masă hiperecogenă cu structură heterogenă cu tendinţa de a ocupa întreg vitrosul cu zone intens reflective determinate de calcificări, axul anteroposterior al globului ocular este normal. În cazul RB fără calcificări se observă masă tumorală neregulată cu reflectivitate difuză, vascularizată. **Leziuni tumorale orbitare –** există 4 modele ecografice de leziuni de masă: chistice, solide, angiomatoase şi infiltrative. Conturul poate fi rotund, bine definit şi să comprime structurile adiacente sau conturul neregulat poate fi sugestiv pentru tumori angiomatoase sau infiltrative. Ecourile interne – ecourile de amplitudine mică în interiorul tumorii indică tumori solide homogene. Tumorile orbitei sunt mai puţin ecogene comparativ cu grăsimea orbitei prezentându-se sub forma unor lacune, limitele putând fi bine conturate sau estompate. Structuri tumorale orbitare: **1.** structuri heterogene foarte ecogene (hemangiomul cavernos capilar, hematomul orbitar necolectat); **2.** structuri dure – moderat ecogene, omogene (tumori primitive, metastaze); **3.** structuri lichide – neecogene, omogene (mucocelul, chistul dermoid). **Tumorile infiltrative** (limfom, carcinom metastatic, sarcom) sunt cel mai dificil de diagnosticat cu ajutorul ultrasunetelor deoarece modificările inflamatorii ale orbitei pot produce aspect similar mai ales dacă edemul inflamator inplică nervul optic şi spaţiul sub-Tenon; acelaşi aspect poate fi greu de diferenţiat şi în caz de cicatrici ale ţesuturilor orbitei după chirurgie anterioară la nivel orbitar. **Tumori chistice – 1.** *mucocel* – rotund, bine conturat, bine demarcat de ţesuturile din jur, modul B – cavitate ultrasonotransparentă, modul A intern ecou liniar; fără absorbţie a ultrasunetelor la nivelul leziunii, ceea ce permite vizualizarea peretelui posterior; **2.** *chist dermoid*; **3.** *hemangiom cavernos* – rotund, bine delimitat (în special marginea anterioară), absorbţie joasă-moderată, ecouri interne de joasă

amplitudine; **4.** *hemangiopericitom*; **5.** *limfangiom chistic*. **Tumori solide –** *tumorile nervului optic* – **1.** rotunde, margine anterioară bine definită, marginea şi extensia posterioară sunt greu de apreciat din cauza absorbției crescute a ultrasunetelor la nivelul leziunii; pe A scan homogenitate acustică cu ecouri de amplitudine mică; **2.** produc lărgirea umbrei sonotransparente determinate de nervul optic, uneori indentarea nervului optic în porțiunea anterioară. **Tumori angiomatoase – 1.** margini neregulate, bună transmitere prin leziunea de masă; **2.** limfangiom difuz – localizarea, mărimea şi granițele se demonstrează cu ajutorul modulului B; transmiterea ultrasunetelor la nivelul leziunii este bună şi nu apare atenuare sonică; prezintă pulsații pe A scan. **Tumori infiltrative – 1.** *limfoame* – contur neregulat, lobulat, demarcate față de țesuturile din jur, conținut solid cu mare capacitate de absorbție a ultrasunetelor, nu se poate obiectiva extensia posterioară a tumorii, homogenitate acustică, ecouri medii ca amplitudine pe A scan; **2.** *carcinom metastatic* – spații infiltrative sonotransparente infiltrative în grăsimea orbitară; **3.** *histiocitom fibros*; **4.** *rabdomiosarcom*. **Pseudotumoră inflamatorie** – pe B scan se observă leziune de masă tumorală în interiorul orbitei şi edem inflamator al structurilor orbitare normale. Caracteristicile acustice sunt similare tumorilor infiltrative: contur neregulat, absorbție puternică a ultrasunetelor.

Avantajele ecografiei în cazul leziunilor tumorale oculoorbitare – ultrasonografia este o metodă neinvazivă, sigură, bine tolerată, puțin costisitoare care oferă avantajul determinării poziției şi distanței tumorii față de structurile oculare. Frecvența mare a ultrasunetelor oferă o rezoluție excelentă de 0-1 la 0,01 mm, iar ecografiile seriate permit urmărirea evoluției leziunii în timp şi măsurarea diametrelor tumorii permițând astfel monitorizarea şi evaluarea tratamentelor de iradiere stereotactică aplicate în cazul tumorilor de mici dimensiuni.

METABOLIC SYNDROME IN HIV INFECTED PATIRENTS WITH FAVORABLE RESPONSE AT ANTIRETROVIRAL THERAPY (Abstract): **Aim:** The assessment of the metabolic syndrome prevalence, as defined by the American Heart Association / The US National Cholesterol Education Program Adult Treatment Panel, (AHA / NCEP III updated), has been made in 68 polyexperimented HIV infected patients that received antiretroviral therapy over 24 months and who have a favorable viroimunologic response (undetectable plasmatic viral load). **Materials and methods:** this cross-sectional analytical study has been carried out on a cohort of 68 patients clinically and paraclinically monitored at the HIV /AIDS Department. **Results:** The response to antiretroviral therapy clinically and paraclinically evaluated after two years from the initiation of the novel HAART scheme has been favourable in all the 68 patients. Only 4 (0.58%) of the patients fulfill the criteria of the metabolic sindrome definition. The statistical analysis does not indicate an increase in the risk of the metabolic syndrome development in these polyexperimented patients, where the clinical symptoms connected with the lipodistrophic syndrome with lipoatrophy are preponderent, associated with different types of antiretroviral drugs. **Conclusions:** The metabolic syndrome criteria are not applicable in the case of HIV infected patients (infected in the first year of life), polyexperimented at HAART therapy with favourable viroimmunologic response. **Key words:** HIV PATIENTS, METABOLIC SYNDROME, HAART

Sindromul metabolic pare a avea o prevalenţă mai mare la pacientul infectat cu HIV faţă de cel neinfectat, supoziţie infirmată printr-o multitudine de studii clinice (1). În populaţia generală prevalenţa sindromului metabolic variază între 22-24% crescând odată cu vârsta (1). Prevalenţa creşte însă la pacientul infectat cu HIV cu tratament antiretroviral

Introducerea terapiei Highly Active Anti-Retroviral Therapy (HAART) a redus semnificativ progresia bolii spre stadiul de boală SIDA, morbiditatea şi mortalitatea asociată cu HIV (2,3). Pe termen lung medicaţia antiretrovirală induce modificări ale metabolismului glucidic, lipidic şi modificări morfologice (acumularea de grăsimi, lipoatrofia) (4). Studii recente de cohortă sugerează o creştere a sindromului metabolic şi a riscului cardiovascular (RCV) la pacienţii cu HAART şi viremie nedetectabilă (5). Pe termen lung nu au fost clar definiţi: rolul HIV, al terapiei HAART şi al

factorilor genetici în generarea modificărilor metabolice ce însoţesc sindromul metabolic, factor de risc cardivascular (1,5). Terapia HAART induce modificări ale metabolismului lipidic: hipercolesterolemia (30%-95%), hipertrigliceridemia (50%-90%), sindromul lipodistrofic (20%-83%), insulinrezistența (25%-62%), diabetul zaharat (5%-10%) şi hipertensiunea (20%-74%) (6,7). Fiecare clasă de medicamente ARV influenţează diferit metabolismul lipidic: inhibitorii de protează sunt asociaţi cu creşterea TGL la peste 25% din pacienţii la un an de la iniţierea tratamentului (8-10), inhibitorii nucleozidici de revers transcriptază sunt asociaţi cu creşterea colesterolului total al LDL-C şi al trigliceridelor iar inhibitorii nonnucleozidici de reverstranscriptază cu creşterea HDL-C, dar pe termen lung cresc LDL-C şi trigliceridele.

MATERIAL ŞI METODĂ

A fost efectuat un studiu transversal pe 68 de pacienţi diagnosticaţi cu infecţie HIV între 1989-1990. La momentul iniţierii noii scheme HAART la subiecţii în eşec terapeutic (viremie plasmatică >1000 copii/ml, scădere accelerată a LCD4, fără infecţii oportuniste manifeste clinic), pacienţii fiind la minim 2 scheme HAART în antecedente. A fost efectuat examenul clinic obiectiv pe aparate şi sisteme initial, apoi din 6 în 6 luni. Examenul clinic a semnalat scăderea ţesutului celular subcutanat la nivelul extremităţilor, la nivel facial, temporal, nazolabial şi genian, semne caracteristice sindromului lipoatrofic. Au fost măsurate circumferinţele braţului, coapsei, toracelui, taliei şi şoldului folosind panglica metrică, talia cu taliometrul şi greutatea cu cântarul şi calculul indicelui de masă corporală (IMC Dubois). În conformitate cu protocolul şi cu consimţământul subiecţilor, probele biologice au fost recoltate dimineaţa „*à jeun*", după cel puţin 12 ore de post. Din lotul studiat 19% au fost la a 2-a schemă, 52% la a 3-a schemă, 27% la a 4-a şi 2% la a 5-a schema HAART. Testele de rezistenţă genotipică (TRG) au fost efectuate la 10 pacienţi, noua schemă HAART fiind în concordanţă cu algoritmul de interpretare a TRG. Au fost analizate datele demografice (vârstă, sex, mediu de provenienţă), nivelul iniţial, dinamica LCD4 şi a viremiei plasmatice (tab. I, II). Evaluarea sindromului metabolic a fost făcută pe baza definiţiei AHA /NCEP III actualizată luându-se în calcul cel puţin trei din următoarele criterii: obezitate abdominală, hipertrigliceridemie, scăderea HDL-C, hipertensiunea arterială, creşterea glicemiei „*à jeun*".

Au fost urmăriţi:

- circumferinţa taliei: barbati ≥102 cm; femei ≥88 cm;
- trigliceride ≥150 mg/dl;
- scăderea HDL colesterolului (HDL-C) la bărbaţi ≤40mg/dl, la femei ≤50mg/dl;
- creşterea tensiunii arteriale ≥130/85 mm Hg sau utilizarea de medicamente antihipertensive;
- glicemia „*à jeun*" ≥110 mg/dl sau utilizarea de medicamente antidiabetice.

A fost evaluată şi Proteina C reactivă ca marker predictiv al riscului coronarian.

Eşantionul studiat fiind mic, analiza statistică s-a bazat pe indicatori statistici descriptivi (valori medii, intervale de încredere 95%) şi teste comparative (*t Student*, odds ratio) folosind programe tip *SPSS*, Microsoft Excel + Analyse-it, $p<0.05$ a fost considerat semnificativ statistic.

REZULTATE ŞI DISCUŢII

Din cei 68 de pacienti înrolaţi, 63% (43) se aflau în stadiul de boală SIDA si 47% (25) în stadiul de infecţie HIV.

La doi ani de la iniţierea ultimei scheme HAART, toţi pacienţii au menţinut un răspuns viroimunologic favorabil (tab. III, IV).

Groups	N	≤	>	Median
VP iniţial	68	0	68	70500,0
VP la 2 ani	68	68	0	46,0
p	<0.0001			

TABELUL V

Valorile obţinute ale parametrilor definitorii pentru sindromul metabolic

talie (cm)	
>102 bărbaţi	0
> 88 femei	0
TA	
≥135/80mmHg	4(0,58%)
HDL - Colesterolul	
bărbaţi ≤40 mg/dl	36(94%)
femei ≤50 mg/dl	28(93%)
trigliceridele ≥150mg/dl	60(88%)
glicemie ≥110 mg/dl	6(0,88%)

Pacienţii evaluaţi au avut o durată medie a terapiei HAART de 14 ani. Din cei 68 de subiecţi analizaţi 4 au risc de a dezvolta sindrom metabolic (p<0,1, nesemnificativ statistic), doi de sex masculin şi doi de sex feminin. Prevalenţa SM a fost de 0,58% (CI 95%). Nu au existat variaţii legate de vârstă, lotul studiat fiind unitar din acest punct de vedere. Sindromul lipodistrofic cu lipoatrofie a fost prezent la 55 (80%) versus 13 pacienţi (20%, p=0,0001). Hipertrigliceridemia a fost prezentă la 88% dintre subiecţi, HDL-C scăzut sub limita de protecţie, peste 90% nefiind diferenţe între sexe. Modificările glicemiei „a jeun", valorile tensiunii arteriale, sunt puţin implicate în definirea SM la acest lot (tab. V). Lipoatrofia ar trebui asociată cu SM deoarece apare ca o consecinţă a redistribuirii prin exces sau pierdere a grăsimilor şi se poate asocia cu insulinorezistenţa. Pacienţii aflaţi în multiplu eşec terapeutic au recuperat parţial deficitul în greutate, cei cu lipoatrofie mai greu şi incomplet (p=0,003), neexistând o corelaţie între modificările distribuţiei grăsimilor în corp şi valorile lipidelor sanguine. Nu a putut fi făcută o corelaţie semnificativă statistică între IMC şi sindromul lipodistrofic. Analiza multivariată arată că stavudina (odss ratio 1,87; CI 95% 1,23-3,12; 0.002) se asociază cu sindrom metabolic. Analiza statistică nu evidenţiază riscul apariţiei sindromului metabolic la aceşti pacienţi, poliexperimentaţi la care predomină manifestările clinice legate de sindromul lipodistrofic cu lipoatrofie,

asociat diverselor clase de medicamente antiretrovirale.

CONCLUZII

Criteriile definitorii ale sindromului metabolic nu sunt aplicabile pentru pacienţii cu infecţie HIV (infectaţi în primul an de viaţă) poliexperimentaţi la HAART cu răspuns viroimunologic favorabil. Multiplele scheme de terapie antiretrovirală la adultul tânăr infectat în primii ani de viaţă generează modificări ale fizionomiei şi metabolismului lipidic, nesemnificativ ale glicemiei „a jeun“ sau provocate influenţând criteriile de încadrare în definiţia de caz. Recuperarea indicilor atropometrici este lentă şi parţială în condiţiile răspunsului sustenabil la HAART. Efectuarea de studii pe cohorte mari de pacienţi din această categorie ar permite identificarea altor criterii de diagnosticare a SM. Rezultatele sunt asemănătoare şi pentru evaluarea riscului cardiovascular. Este posibil ca lotul studiat, redus numeric, să influenţeze rezultatele statistice obţinute. Noile clase de medicamente antiretrovirale par a avea, cel putin pe termen scurt, reacţii adverse reduse asupra metabolismului lipidic, glucidic şi al valorilor tensiunii arteriale.

PERCUTANEOUS NEPHROSTOMY COMPLICATIONS IN OBSTRUCTIVE RENAL FAILURE (Abstract): **Objectives**: The study aimed to identify the complications recorded at the patients with obstructive renal failure treated with percutaneous nephrostomy (PCN). **Material and method**: The retrospective study investigated the data of 244 patients admitted in our department and treated with percutaneous nephrostomy for obstructive renal failure during January 2005 – December 2007. Demographical data, investigation, indication, complications and hospital stay were recorded. **Results**: Median preoperative/discharge haematological values were hematocrit 27.4% comparing to 25.8% and haemoglobin 9.9g% comparing to 9.3g%. An anaemic syndrome was noted at admission time in 161 (65.9%) patients and at discharge time 202 (82.8%). 126 (51.6%) patients were treated with blood transfusion with an average dose of 2.47 red blood cell units per patient. In 25 (10.1%) patients the nefrostomy tube was clamped in order to control the postoperative bleeding. The median hospitalization time was 8.7 days with a median ICU stay of 3.3 days. The recorded mortality was 3.2% (8 patients) with an average time of 5.8 days between the operatory time and exitus time. **Conclusions:** The most frequent causes of obstructive renal failure necessiting percutaneous nephrostomy are malignancies. Preoperative anaemic syndrome is aggravated in the postoperative period and frequently need red blood cell administration. In experienced hands, PCN catheter placement is safe and usually successful **Key words**: RENAL FAILURE, PERCUTANEOUS NEPHROSTOMY , COMPLICATION

Insuficiența renală (IR) postrenală se întâlneşte la aproximativ 5% din cazurile de IR. Obstrucția tractului urinar determină insuficienta renală în cazul interesării bilaterale a fluxulului urinar renal cu excepția unei disfuncții renale preexistente când obstrucția poate interesa un singur rinichi (1).

Abordarea terapeutică în urgență a obstrucției tractului urinar superior include tehnicile minim invazive: cateterismul ureteral sau nefrostomia percutanată.

Nefrostomia percutanată constă în plasarea ghidată imagistic a unui cateter în sistemul colector renal (2).

Plasarea unui cateter de un calibru suficient pentru a asigura drenajul adecvat al sistemului colector sau a per-mite dilatarea traiectului şi efectuarea procedurii intervenționale planificate defineşte nefrostomia percutanată reuşită. Rata de succes a procedurii percutanate este de 98%–99%

fiind mai redusă la pacienții cu sistem colector nedilatat, litiaza renală complexă sau calculi coraliformi (3,4,5).

Prima descriere a nefrostomiei percutanate a fost făcută în 1955 (6) sub forma unei proceduri efectuate sub o ghidare imagistică limitată motiv pentru care a fost acceptată cu anumite rezerve;

Perfecționarea instrumentarului utilizat precum și a tehnicilor radiologice intervenționale au permis extinderea acestui procedeu terapeutic. În România prima intervenție percutanată renală a fost efectuată în 1985 în Clinica Urologică Târgu Mureș de Profesorul Radu Boja.

Nefrostomia chirurgicală deschi-să de decompresiune a reprezentat tratamentul standard al obstrucției maligne ureterale în etapa predecesoare impunerii chirurgiei minim invazive (7), ulterior această opțiune terapeutică a fost aproape în totalitate înlocuită de nefrostomia percutanată datorită complicațiilor cu incidență redusă (8,9).

Complicațiile asociate cu NSP sunt puține și de obicei minore. În general rata complicațiilor procedeului de nefrostomie percutanată este sub 10% (4,10), dar la pacienții cu neoplazii avansate au fost raportate frecvențe crescute ale complicațiilor (4,10,11) explicate prin statusul biologic precar și diateza hemoragică uremică.

Complicațiile majore după abordul percutanat se situează în jurul cifrei de 5% (12,13), iar complicațiile minore se întâlnesc în peste 70% din cazuri, în timp ce mortalitatea variază între 0,5-1%. Cea mai întâlnită complicație este hemoragia antrenând o pierdere parțială a funcției renale sau chiar nefrectomia și impunând frecvent transfuzii de sânge cu riscurile asociate de hepatită și infecție cu HIV.

Reducerea complicațiilor hemoragice este posibilă prin obținerea unui traict care abordează sistemului colector prin fornix sau vârful papilei unui calice posterior la care se ajunge străbătând teritoriul relativ avascular dintre diviziunile anterioare și posterioare ale liniei Brödel (7,8).

OBIECTIVE

Scopul studiului a fost de a evalua complicațiile drenajului urinar percu-tan în abordarea terapeutică a pacienților cu insuficiență renală obstructivă.

MATERIAL ŞI METODĂ

Lucrarea reprezintă un studiu retrospectiv al experienței Clinicii Urologice Iași în soluționarea prin abord percutanat renal a patologiei obstuctive urinare asociate cu insuficiența renală. Au fost incluși în studiu 244 de pacienți cu insuficiență renală obstructivă internați in Clinica de Urologie și Transplant Renal Iași la care s-a practicat nefrostomie percutanată în perioada ianuarie 2005 – decembrie 2007.

Selecția pacienților s-a efectuat pe baza diagnosticului clinico-imagistic și biologic (uree,creatinină) de insuficiență renală obstructivă.

Procedurile intervenționale s-au realizat sub control imagistic asigurat de un echipament radiologic mobil (Siremobil Compact L Siemens) și un ecograf BK MiniFocus. Pentru drenajul urinar s-au utilizat catetere de uz general (sonde cu balonaș tip Foley 20 Ch) și dedicat (truse de nefrostomie a minima 8, 12F), fire ghid 0,038". Dilatarea acută a traiectului s-a realizat cu dilatatoare fasciale de dimensiuni progresive pană la 12 F în cazul NSP a minima, și respectiv cu setul de dilatatoare Amplatz în cazul montării unor sonde autostatice tip Foley.

Parametrii analizați în prezentul studiu au fost reprezentati de: afecțiunea care a

determinat obstrucția urinară, complicațiile postoperatorii, hematocrit, hemoglobină, urocultură, tipul de cateter utilizat.

Prelucrarea statistică a datelor a fost realizată prin utilizarea programului SPSS 17.0 for Windows.

REZULTATE ŞI DISCUȚII

Lotul de pacienți a fost alcătuit din 244 de pacienți (121 femei şi 123 bărbați) diagnosticați cu insuficiență renală obstructivă). Vârsta medie a pacienților a fost de 61,14 cu limite între 21 şi 90 de ani. Mediul rural a fost preponderent (59,42% rural vs 40,78% urban).

Evaluarea patologiei care deter-mină obstrucția aparatului urinar ce impune efectuarea NSP obiectivează o pondere majoră a patologiei neoplazice, afecțiuni în care tentativele de protezare endoureterală (stent ureteral JJ) eşuează din cauza condițiilor locale sau datorită evoluției ulterioare nefavorabile în condițiile drenajului urinar intern(recuperare funcțională nesatisfăcătoare, complicații infecțioase). Cele mai frecvente neoplazii sunt cancerul de col uterin, tumorile vezicale infiltrative şi cancerul de prostată local avansat (tab. I).

TABELUL I

Etiologia obstrucției urinare ce a impus efectuare nefrostomiei percutanate pentru tratamentul insuficienței renale

Etiologia obstrucției urinare	Nr. cazuri	Frecventa
LITIAZĂ URETERALĂ	19	7,79%
HIDRONEFROZĂ CONGENITALĂ	6	3,46%
LITIAZĂ RENALĂ	2	0,82%
CISTITĂ INCRUSTATĂ	1	0,41%
FIBROZĂ RETROPERITONEALĂ	1	0,41%
MEGAURETER OBSTRUCTIV	2	0,82%
TUBERCULOZĂ URINARĂ	7	1,86%
STENOZĂ URETERALĂ MULTIPLĂ	3	1,23%
UROPIONEFROZĂ	4	1,64%
NEOPLASM COL UTERIN	77	31,54%
NEOPLASM VEZICAL	53	21,72%
NEOPLASM PROSTATIC	31	12,70%
NEOPLASM RECTAL	7	1,86%
NEOPLASM COLON	1	0,41%
NEOPLASM MAMAR	1	0,41%
NEOPLASM OVARIAN	3	1,23%
NEOPLASM SIGMOIDIAN	4	1,64%
NEOPLASM UTERIN	1	0,41%
NEOPLASM VEZICAL + NEOPLASM PROSTATIC	2	0,82%
TUMORĂ PELVINĂ NEPRECIZATĂ	13	5,32%
TUMORĂ VAGINALĂ	1	0,41%
ALTE NEOPLAZII	5	2,05%

Nefrostomia percutanată este recunoscută ca fiind o intervenție cu risc hemoragic semnificativ. Sângerări asimptomatice clinic sunt frecvent întâlnite, hematuria moderată este prezentă la aproximativ 50% dintre pacienți după poziționarea NSP (14) în timp ce sângerările retroperitoneale documentate prin tomografie computerizată se întâlnesc în 13% din abordurile percutanate renale (15). Hemoragiile ce necesită transfuzii sanguine au o incidență de 1-4 % (4,5,12,16) . La 10,12% din pacienți supuşi intervenției s-a inregistrat apariția unei hematurii importante ce a necesitat manevre de tamponadă locală (clamparea sondei de nefrostomie) şi mijloace de compensare hematologică. La 126 de pacienți s-au efectuat transfuzii cu o medie de 2,47 unități de sânge per pacient.

Leziunile vasculare (17,18) care impun embolizare sau nefrectomie sunt întâlnite în 0.1-1% din cazuri.

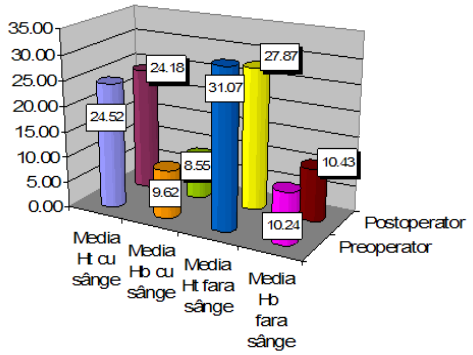

Fig.1. Bilanțul hematologic al pacienților care au primit sânge *vs.* pacienți netransfuzați

Alte complicații asociate NSP sunt mult mai rare şi include leziunile colonului (19,20). Perforația colonului citată în 0,2% (20) (retroperitoneală) a fost identificată într-un singur caz (0,4%) la 5 luni de la efectuarea abordului percutanat fiind soluționată conservator.

Nu au fost consemnate leziuni splenice (21) sau puncții ale veziculei biliare (22). Complicațiile pleurale posibile în abordul percutanat (pneumotorax, hemotorax, pleurezii – 0,1 – 0,2% (4,17)) nu au fost intâlnite în lotul studiat deoarece nu s-au impus traiecte de nefrostomie supracostale.

Şocul septic raportat în literatură cu o incidență de 1-3% (4,23,24) a fost clinic manifest în 22 de cazuri 9,82%, pacienții fiind frecvent infectați la internare.

Eşecul plasării nefrostomiei s-a înregistrat în 3,24% din cazuri impunându-se puncționarea sistemlui colector cotrolateral sau intervenția unui medic mai experimentat.

Depoziționarea precoce a sondei s-a înregistrat în 9 cazuri (3,68%).

Complicațiile tardive apar datorită disfuncțiilor cateterului (depozitionare sau ocluzie) (25) şi se întâlnesc la 40-50% din pacienți; acestea scad cu calibrul crescut al cateterului, materiale mai moi şi prezența mijloacelor autostatice.

Cel mai frecvent se constată depoziționarea cateterului sau ocluzia acestuia. Manifestările clinice ale blocajului cateterului sunt: scurgerea de urină pe lângă cateter, creşterea ureei şi creatininei, pielonefrită acută. În aceste condiții se impune înlocuirea cateterului, lucru care se poate efectua în condiții de spitalizare de zi, cu excepția cazurilor de pielonefrita acută.

Au fost înregistrate 8 decese (3,27%) survenite la un interval mediu de 5,79 zile de la momentul operator. În 50% din cazurile de deces cauza determinantă a fost sindromul de disfuncție multiplă de organ, un singur caz de deces a survenit în contextul unui hematom lombar voluminos.

CONCLUZII

Numărul complicațiilor înregistrate, mai ales a celor majore (hemoragice şi infecțioase) a fost relativ redus având în vedere că

nefrostomiile percutanate au fost practicate, în cele mai multe cazuri, la pacienți aflați în condiții clinice grave.

Ghidajul combinat: ecografic și fluoroscopic, utilizat pentru realizarea puncției percutanate a facilitat obținerea unui abord corect al sistemului pielo-caliceal și consecutiv posibilitatea efec-tuării unei dilatații acute a traiectului de nefrostomie până la un diametru ce a permis poziționarea unor sonde autostatice cu balonaș (Foley).

Utilizarea sondelor Foley asigură o întreținere facilă prin prețul redus al materialelor, risc redus de depoziționare și prin posibilitatea înlocuirii sondelor în condiții de ambulator .

Pacienții care beneficiază de această modalitate de tratament necesită transfuzii repetate în scopul redresării sindromului anemic determinat de malignitate, insuficiența renală și accentuat de hemoragiile declanșate de intervenția percutanată.

ATYPICAL MENINGIOMAS OF CEREBELLOPONTINE ANGLE: A FIVE CASE SERIES (Abstract): Cerebellopontine angle (CPA) meningiomas represent a subset of posterior fossa tumors accounting approximately 10% of all brain tumors, and out of all these, meningioma is the second most common tumor of the CPA. Surgical treatment of CPA meningiomas is challenging because of their relationship with important and vital neurovascular structures of the CPA. **Aim:** Identification of clinical, neuroimaging and surgical features of atypical CPA meningiomas. **Material and methods:** Out of all the 1287 intracranial meningiomas diagnosed and operated in "Professor Dr. N. Oblu" Emergency Clinical Hospital Iasi, from 1990-2015 were identified 44 CPA meningiomas. Of these were identified 5 atypical meningiomas (AM) of CPA. The results of our five-case series were compared to those of the existing studies. **Results:** This is an observational clinical study for five cases of atypical CPA meningiomas. CPA meningiomas have distinct clinical syndromes, associated with anatomical localization. Compared to the previous studies, the number of atypical CPA meningiomas from our series is higher, with average duration between the onset of symptoms and admission longer. As well as in literature, in our case series the retro sigmoid approach was preferred and the only subtotal tumoral resection of AM were those with extension towards the ventral petrous face and facial palsy was the most common postoperative complication. **Conclusions:** Surgical treatment of atypical CPA meningiomas has become increasingly safe, but these tumors remain challenging lesions, and the resection of these tumors is associated with increased rates of complications. **Keywords:** ATYPICAL MENINGIOMA, WHO GRADE II MENINGIOMAS, CEREBELLOPONTINE ANGLE MENINGIOMAS, POSTERIOR FOSSA MENINGIOMAS.

CPA tumors represent approximately 10% of all brain tumors (1). Out of all these, meningioma is the second most common tumor of the CPA after vestibular schwannoma, counting 5-15% of all the tumors of this region (2).

CPA meningiomas arise from epithelial cells, which aggregate in clusters around the tips of arachnoid villi. In CPA, they are located within the internal auditory canal, in the region of *porus acousticus*, *clivus*, *exit foramina* of the trigeminal nerve (Meckel's cavum), superior and inferior petrosal sinuses, sigmoid sinus, jugular foramen and torcula (3, 4, 5, 6, 7).

Like other intracranial meningiomas in general, CPA meningiomas are typically slow growing, usually in a different direction and can produce symptoms when they comprise nerve structures or cranial nerves (8). Due to this slow growing, CPA meningiomas can produce pressure indentation in the cerebellum and brainstem, but these can adapt themselves and undergo considerable distortion (7), so that meningiomas can reach gigantic dimensions, which may exceed 100 mm at the time of diagnosis (9).

Meningiomas arising within the CPA can displace or surround the vessels and cranial nerves rather than invade them, but depending on the histology of meningiomas, they can strongly adhere to these structures (5, 7), due to which these tumors represent a very important surgical challenge. Despite the advanced clinical techniques, the maximal surgical resection can't be performed without determining the patient face a high morbidity and mortality risk (2), and these are attributed precisely to the way the tumor surrounds or infiltrates cranial nerves and/or brainstem (10). Thus, the meningiomas of these challenging locations have higher subtotal resection complications rates (8, 11, 12, 13) and represent a challenge even in the hands of expert neurosurgeons (14).

MATERIAL AND METHODS

There were identified 5 CPA meningiomas diagnosed and operated in "Professor Dr. N. Oblu" Emergency Clinical Hospital Iasi, Romania, from 1990 to 2015. Also, specialty literature has been revised and the key words which were identified are *atypical meningioma* and *cerebellopontine angle meningioma*, *skull base meningioma* and *posterior fossa meningioma*. The results of our five-case series were compared to those of the existing studies.

RESULTS

Out of all the 1287 intracranial meningiomas diagnosed and operated in "Professor Dr. N. Oblu" Emergency Clinical Hospital Iasi, from 1990 to 2015, there were identified 44 CPA meningiomas. These represent a percentage of 3.41% from the total of diagnosed and operated meningiomas in our hospital from 1990 to 2015. According to the WHO grade of CPA meningiomas, this consists mainly of WHO grade I meningiomas, counting 84% (37 cases), followed by WHO grade II meningiomas (AM), counting 11.36% (5 cases) and WHO grade III meningiomas, counting 4.5% (2 cases) (fig 1).

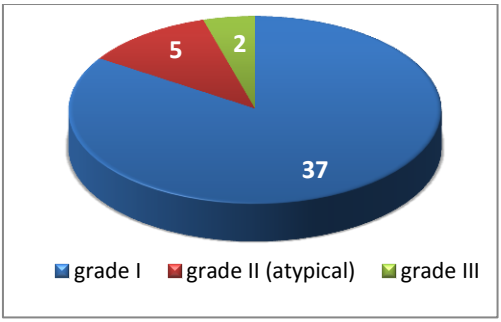

Fig. 1. CPA meningiomas distribution according to the WHO grades (1990-2015).

Case 1. Female patient aged 59 is hospitalized for headache and nausea, vertigo, gait instability, adiadochokinesia and hy-

poacusia with mild CN XII paresis for thirty months. Subsequent head-MRI demonstrated a 44 mm heterogeneously enhancing lesion rising from posterior petrous face, which occupies CPA (fig 2). The patient underwent left retro sigmoid craniotomy with gross total resection (GTR). Postoperatively, the evolution was favorable with left facial palsy and swallowing difficulty. On the sixth day of surgery, the patient began suffering from febrile syndrome and diarrhea (further confirmed *Clostridium difficile),* tachypnea, finally causing septic shock and death.

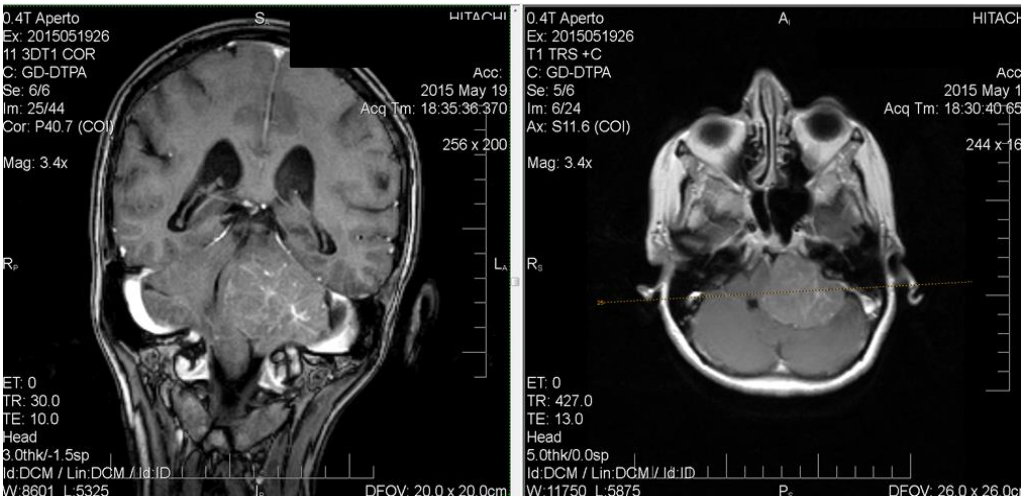

Fig. 2. Case 1. Preoperative coronal and axial T1-weighted images with contrast showing a large left CPA atypical meningioma.

Case 2. Female patient aged 48, comes to a consultation with a 2-year headache history, left cerebellar dysfunction, left hypoacusia, dysphonia, hypoesthesia in the left extremity and hemifaces, characterized by a two-week acute evolution. A head-CT revealed a 40 mm left CPA mass (fig 3. A). The performed surgery involved a left retro sigmoid craniotomy with subtotal gross resection (STR) (fig 3. B). Two days after the surgery, the patient developed hydrocephaly and underwent right frontal external ventricular drain, which was subsequently suppressed. Clinical evolution was favorable, with MRI follow-up demonstrating the increase in size of the lesion (fig 4. A). Eight years after the surgery, the patient comes again for gait instability and left-sided hemiparesis. Head-MRI scan highlighted tumor growth (fig 4. B. C), but the patient refuses surgical intervention.

Case 3. Female-patient aged 57 is hospitalized for a 12-month headache, hypoacusia and cerebellar syndrome. Head-MRI examination emphasized a left CPA meningioma, measuring 45 mm (fig 5). The patient underwent left retro-sigmoid craniotomy with STR, followed by a transient facial palsy.

Case 4. Female-patient aged 75 is admitted for intracranial hypertension syndrome, progressive spastic paraparesis, gait instability, left hypoacusia, with a nineteen-month insidious onset. Head-MRI scan revealed a meningioma of the free

margin of the tentorium developing infratentorial in the left CPA (fig 6. A). The patient underwent left sub temporal approach with GTR and partial resection of the tentorium infiltrated, followed by a favorable clinical evolution and remission of symptoms. MRI follow-up at six months (fig 6. A) and twelve months (fig 6. B) demonstrates the absence of recurrence.

Case 5. Female-patient aged 40 is hospitalized for right hypoacusia, disorder of equilibrium, vertigo, lasting for approximately 24 months, which add acute headache lasting for 7 months prior to the admission. MRI scan revealed a right sigmoid sinus and superior petrosal sinus meningioma with infratentorial extension in the right CPA (fig 7. A. B). The patient underwent left retro sigmoid craniotomy with GTR (fig 7. C). The evolution was favorable with left facial palsy which was subsequently remitted.

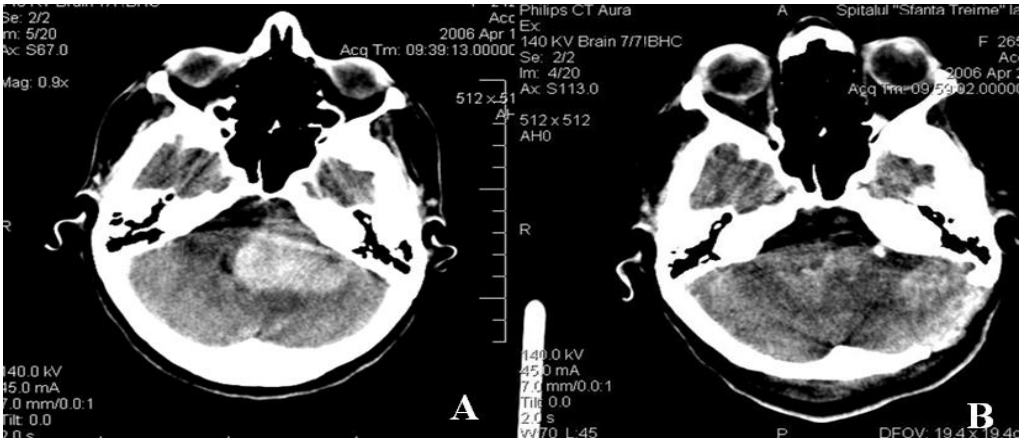

Fig. 3. Case 2. Preoperative (A) and postoperative (B) axial CT images with contrast.

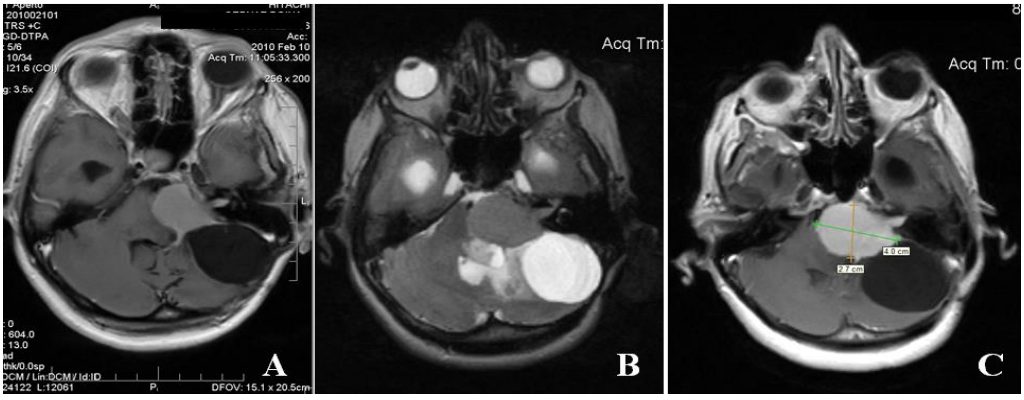

Fig. 4. Case 2. Left CPA atypical meningioma 4 years after surgery (A), 8 years after surgery (B) and 9 years after surgery (C). The increase in size by 3 mm of AM is observed 4 years after surgery (B) and stationary images between (B) and (C).

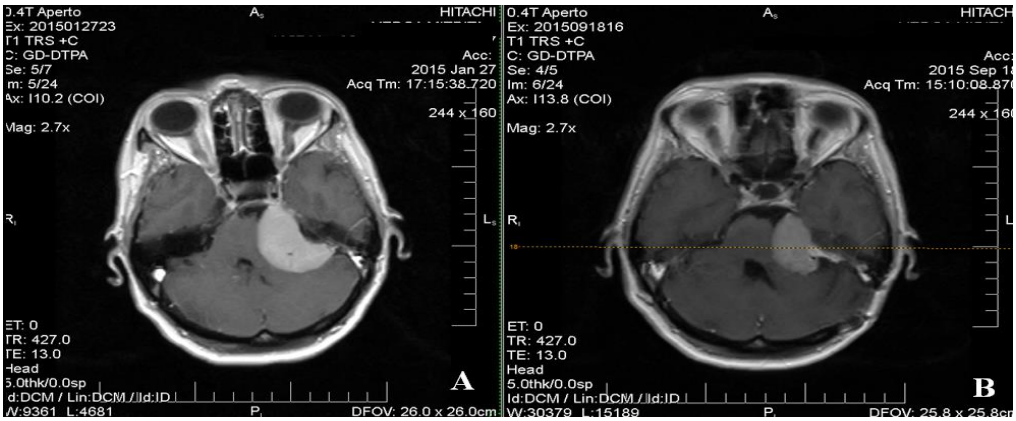

Fig. 5. Case 3. Left CPA atypical meningioma. Preoperative (A) and postoperative (B) axial T1-weighted images with contrast.

Fig. 6. Case 4. Atypical meningioma of the free margin of the tentorium with extension in the left CPA (A). MRI scan at six months (B) and twelve months (C) demonstrates the absence of tumoral recurrence.

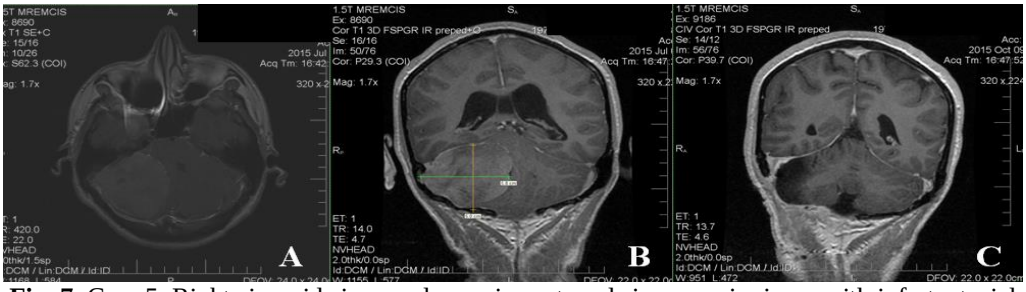

Fig. 7. Case 5. Right sigmoid sinus and superior petrosal sinus meningioma with infratentorial extension in the right CPA (A), (B). Postoperative MRI (C).

DISCUSSION

Out of the total of 44 CPA meningiomas operated from 1990 to 2015 in "Professor Dr. N. Oblu" Emergency Clinical Hospital Iasi, Romania, the AM represent only 11.36% (5 atypical CPA meningiomas) of them, compared to the 1-12.2% percentage reported in the preexistent studies (9, 15, 16, 17, 18, 19, 20, 21, 22) (tab. I). Although the number of CPA meningi-

omas, as they mentioned in literature, ranges from 28 to 193 of cases, and the follow-up time were like the ones in our series, studies could not identify more than 3 atypical CPA meningiomas for at least 20 years (9, 15). We noticed that compared to the literature, the number of atypical CPA meningiomas from our case series is higher, and this could be justified by the geographical proximity to Chernobyl and secondary irradiation to the disaster (23).

In 1917, Cushing described the *syndrome of the cerebellopontine angle* as being represented by symptom progression: 1) auditory and vestibular changes, 2) headache, 3) ataxia, 4) involvement of adjacent cranial nerves, 5) hydrocephalus, 6) dysarthria and dysphagia and 7) cerebellar and brain stem signs (24, 25). Later, Bartels and Arrington (1994) described extensively the typical course of CPA syndrome as: hearing loss, balance disturbance, altered facial sensation, facial pain, and later nystagmus, impaired coordination, facial palsy, swallowing difficulty, impaired vision and eventually long tract signs (26).

TABLE I
Number of atypical meningiomas of the CPA in the main studies (2005-2018).

Authors, Year	Follow-Up Period	CPA Meningiomas	AM	Percent (%)
2018, Magill (15)	1991-2015	51	1	2.0%
2017, He (16)	2012-2015	49	1	2.0%
2017, Lynch (9)	1986-2014	28	3	12.2%
2015, Gao (17)	2010-2013	193	2	1.0%
2013, Agarwal (18)	2005-2013	34	3	8.8%
2013, Nowak (19)	2002-2011	48	2	4.1%
2011, Baroncini (20)	1994-2007	69	3	4.0%
2009, Qu (21)	1996-2006	42	1	2.3%
2005, Roser (22)	1978-2002	74	2	2.8%

As for the early symptomatology of CPA meningiomas, this often consists of complicated symptoms and the first ones are: headache, vertigo or hearing loss and tinnitus, often neglected by patients (16). This makes the time between early symptoms and admission long, and patients to present with large intracranial meningiomas. Regarding the CPA meningiomas, in literature studies the average duration between the onset of symptoms and admission was different: 7.0 months (range 0.1-120 months) (18), 15.9 months (range 1-60 months) or 19.4 months (16), compared to our average period of 21.8 months which is higher (range 19-30 months). The average duration for our case series is longer probably because the other series (16, 18) included all WHO grades meningiomas (grade I, II and III), while our series contains only grade II (AM).

The three most commonly seen complaints in all the four cases from our study were: CN VIII nerve findings (hearing disturbance), headache and cerebellar syndrome in accordance with literature (16). Regarding cranial nerves injury in atypical CPA meningiomas, CN VIII was the most frequently affected by tumors in our series, followed by CN XII (case 1) and CN V, CN IX, CN X and CN XI (case 2), symptoms of lower cranial nerves present only in two cases of posterior face petrous meningiomas (case 1 and 2) (tab. II).

TABLE II
Symptomatology of CPA meningiomas

	Case 1	Case 2	Case 3	Case 4	Case 5
ONSET	30 months	24 months	12 months	19 months	24 months
CN V	-	hemifacial hypoesthesia	-	-	-
CN VIII (HYPOACUSIS)	+	+	+	+	+
CN IX, X, XI, XII	unilateral hypoglossal nerve palsy	dysphonia	-	-	-
INTRACRANIAL HYPERTENSION SYNDROME	+	+	+	+	+
CEREBELLAR SYNDROME	+	+	+	+	
PYRAMIDAL SYNDROME	hyperkinetic reflexes, Babinski -	-	-	progressive spastic paraparesis	-

Moreover, literature records, in the case of CPA meningiomas, the involvement of CN VIII in a high percentage 50-70% (5, 7, 25, 27, 28, 29, 30), aspect confirmed by our series of cases also, hearing disturbance being present to all the patients. In addition to this, the deficits of one or more cranial nerves (CN V to XII) were found in literature in a percentage that involves 30% of the patients in the case of CPA meningiomas (5, 7, 25, 28, 29, 30, 31). Despite this, it is not difficult to notice that regardless the large dimensions of CPA meningiomas indicated by radiographic studies, the involvement of cranial nerves except of CN VIII is very low, being present in only two cases (posterior petrous face meningiomas, case 1 and case 2).

Cerebellar signs (ataxia, adiadochokinesia) were reported in literature in a variable percentage of 30-90% in the case of CPA meningioma (7, 25, 27, 28, 30, 32), also present in all the five cases from our study.

MRI data offers important information to the neurosurgeon about the dislocation of the cranial nerves or other anatomical structures (33, 34). As in literature, meningiomas of the CPA from our series are broad-based/sessile with dural tail (35, 36), while dural insertion was discovered intraoperatively, since the evaluation of preoperatively meningioma dural insertion is difficult to obtain (37).

TABLE III
CPA meningiomas diameters in the main literature studies (2011-2018).

	Diameter (mm)	Average (mm)
2018, Magill (15)	8-62 mm	30 mm
2018 Spena (14)	22-51 mm	37 mm
2017, He (16)	40-55 mm	-
2017, Lynch (9)	20-105 mm	-
2013, Agarwal (18)	9-46 mm	23 mm
2013, Nowak (19)	25- >40 mm	-
2011, Baroncini (20)	28-33 mm	30 mm (+/-11mm)
2011, Peyre (41)	18-45 mm	25 mm

Due to the non-specific symptomology at the moment of the diagnosis, meningiomas have greater dimensions than 44 mm (case 1), 40 mm (case 2), 45 mm (case 3), 32 mm (case 4) and 58 mm (case 5), with the average of 43.8 mm, higher than the average in studies (tab. III).

CASE 1, CASE 2, CASE 3

Posterior petrous face meningiomas in the CPA represent a surgical challenge due to their proximity to the cranial nerves, brainstem and cerebellopontine angle vasculature (8, 12, 38). The posterior petrous face of the temporal bone is somewhat unique in relation with the venous sinuses, because the superior and inferior petrosal, cavernous and sigmoid form a ring which surrounds this posterior face (39). Usually, these tumors have large dimensions when identified, mostly over 30 mm (39), which makes it difficult to establish anatomical relationships. In the case of our series, the two out of three petrous face meningiomas were gigantic with many symptoms like lower cranial findings and signs of brainstem and cerebellar compression (tab 2). Also, studies from literature have shown that middle petrous face tumors (along with middle and posterior petrous locations, most frequently presents with hearing loss and vestibular symptoms (15, 40), same as in the case of our patients. In case of meningioma extension towards the ventral petrous face, because of the difficulties encountered in safely removing, the rate of GTR is lower for this tumor groups than in retro meatal tumors (41), as in two of our cases where STR was performed (case 2 and case 3). Case 2 has developed post-operative hydrocephalus which was subsequently remitted, aspect recorded in literature in the petrous face meningioma case, especially in those with posterior extension (15).

CASE 4

Meningiomas along the free tentorial margin with extension in CPA present a high surgical difficulty, because the tentorial notch is not attached of any bone structures and it encircles the peri mesencephalic cistern which contains important vascular and neural structures (42). The lateral incisura space contains anterior and posterior choroidal arteries and trochlear and trigeminal nerves (42). Meningiomas localized in the lateral incisura space are most frequently accessed by a sub temporal approach, since it offers the most direct and shortest route, even though complications in the temporal lobe retraction may arise (42). The preoperative venogram is important in preserving the vein of Labbé (43, 44, 45).

Infratentorial meningiomas have large dimensions at the moment of their diagnosis and this is because the infratentorial symptoms, like headache and vertigo, are non-specific (46). In the case of our patient, the 24-months onset symptoms consisted in headache and gait instability, late onset of hypoacusia, a month before hospital admission (tab 2). In these cases, sub temporal approach gives the possibility of total resection of tumor, both of supra and infratentorial components (fig 6. B).

CASE 5

Meningiomas with dural attachment over the transverse-sigmoid junction with CPA extension should be differentiated from the meningiomas of the cerebellar convexity, tentorium and petrous bone with marginal attachment to the venous sinuses, although a major part of the studies includes them all in these main groups (32, 39, 47, 48, 49). At this level, as well as

along the transverse sinus and periocular region, arachnoidal cap cells are more relatively abundant than in other parts of the posterior fossa (50, 51).

The localization of the meningiomas away from the cranial nerves, brainstem and fourth ventricle with cerebrospinal fluid pathway, determines the lack of neurological symptomology, or makes it poor and non-specific (52), characterized by headache, vertigo and hypoacusia, like in the case of our patient (case 5) (tab 2). In managing these types of meningiomas, the close relationship with transverse, sigmoid and petrous sinuses is the main issue, but, despite of all these, the superficial location away from the cranial nerves and brainstem involves a low surgical risk when venous sinuses are preserved (52).

Some of the authors consider that the invasion of the venous sinuses must be treated conservatively (53), while others suggest an aggressive approach, with sinus resection and its reconstruction (43, 54, 55, 56, 57). Nevertheless, aggressive management can have a potential serious risk of intraoperative venous infarction and the reconstruction of the superior petrosal sinus outflow into the transverse-sigmoid sinus junction is a difficult one (52).

The residual tumor nodules within the sinus lumen can be treated by radiosurgery, which is a useful adjuvant treatment in subtotal resections or tumor regrowth (58, 59, 60, 61).

In the past ten years, studies of skull base meningiomas and particularly a CPA meningioma focused mainly on functional outcome and life quality (62, 63, 64, 65). Therefore, in our series, facial palsy was the most common postoperative complication, and the functional reeducation may be helpful for the patient (66).

In this regard, recent studies have shown that a complete resection with dura and underlying bone, which corresponds to Simpson grades I and II, has not been positively correlated to a lower recurrence rate in relation to skull base meningiomas (67). Thus, in an era of multimodal treatment, GTR is not mandatory to obtain a good outcome and good tumor control (68). Moreover, residual tumor can be controlled by a conservative treatment, such as radiotherapy, even if atypical CPA meningiomas or higher grades of histopathology have an increased recurrence risk (16). In recent years, meningioma cell biology has progressed significantly and developed a various therapy for adjuvant interventions (69) and anti-proliferative activity agents against meningioma such as flavones and flavanols from wine (70, 71, 72).

Of the five AM of the CPA, only three were gross total resected and two subtotals resected, due to extension towards the ventral petrous face and intrinsic difficulties (tab 4). Retro sigmoid approach is perhaps one of the most commonly used surgical approach for resection of CPA meningiomas (28, 73); 4 of our patients were operated using this approach, while one of them underwent sub temporal approach (tab 4). When approaching a CPA meningioma, should be considered: its expansion to the internal auditory canal, tentorial attachment, invasion of the cavernous sinus and its expansion towards the jugular foramen (28, 73). The preservation of arachnoidal plane and incorporation of arterial branches of the CPA are also important in choosing the best surgical strategy.

As for the resectability rate, petrous meningiomas WHO I have a greater GTR rate than WHO II or gigantic meningiomas, due to the preserved arachnoid layer pro-

tecting the neurovascular structures of CPA and brainstem (74). In addition to this, progression-free survival in WHO grade II is lower compared to WHO grade I (74). Moreover, AM are known for their tendency to relapse after the surgery (75).

TABLE IV
Characteristics of surgery and postoperative complications

Patient	Age, Sex	Tumor Size	Tumor Location	Surgical Approach	Resection	New CN Deficit
1	59, F	44 mm	L	Retro sigmoid	GTR	facial palsy, swallowing difficulty
2	48, F	40 mm	L	Retro sigmoid	STR	-
3	57, F	45 mm	L	Retro sigmoid	STR	facial palsy
4	75, F	32 mm	L	Sub temporal	GTR	-
5	40, F	58 mm	R	Retro sigmoid	GTR	facial palsy

Literature studies reported that large meningiomas (>30 mm) of the CPA are associated with a rate of complications (76). In the case of our series, all the CPA meningiomas measure less than 30 mm in diameter, and the postoperative complications consisted in CN VII paralysis (case 1, case 3, case 4) and transient swallowing difficulty (case 1).

CONCLUSIONS

Cerebellopontine angle meningiomas have distinct clinical syndromes, associated with anatomical localization. Compared to the previous studies, the number of atypical CPA meningiomas from our series is higher, with average duration between the onset of symptoms and admission longer. As well as in literature, in our case series the retro sigmoid approach was preferred and the only subtotal tumoral resection of AM were those with extension towards the ventral petrous face and facial palsy was the most common postoperative complication. Surgical treatment of atypical CPA meningiomas has become increasingly safe, but these tumors remain challenging lesions, and the resection of these tumors is associated with increased rates of complications.

3. Spitalul Clinic de Obstetrică şi Ginecologie "Cuza-Vodă" Iaşi

A COMPLEX STUDY ON *PLACENTA PRAEVIA* (Abstract): **Material and methods:** The study was carried out on 53 cases with *placenta praevia*, admitted to the "Cuza Vodă" Obstetrics and Gynecology Hospital, Iaşi, where the prevalence was 3.84% between 2006 and 2009. **Results**. The onset, increased with parity, was during the 8th month (30.19%), with hemorrhage (77.35%). An obstetrical pathological history was found in 33 cases (62.26%).
Key words: PLACENTA PRAEVIA, MATERNAL FETAL RISK, GESTATIONAL MANAGEMENT

Placenta praevia rămâne în atenţia specialiştilor prin complicaţiile patologice materne şi fetale şi prin decesele determinate de anormalitatea inserţională placentară (1, 2,3,4). Incidenţa cazurilor de *placenta praevia* este corelată, în special, cu vârsta (creşte de 3-4 ori la gravidele peste 35 de ani, comparativ cu cele între 15-24 de ani, indiferent de paritate) şi cu paritatea (creşte de 3 ori la marile multipare, comparativ cu primiparele). De asemenea, incidenţa este crescută în sarcinile gemelare, comparativ cu cele unice, din cauza întinderii mari a sediului implantaţiei (5,6).

Factorii etiopatogenici implicaţi în apariţia cazurilor de *placenta praevia* sunt evidenţiaţi prin două ipoteze, care nu se exclud reciproc şi care se referă la implantaţia joasă (*placenta praevia* primară), posibil a fi determinată de neconcordanţa între ritmul de diviziune şi progresiune tubo-uterină a blastocistului şi stadiul de pregătire pentru nidaţie a endometrului, prin insuficienţa secretorie a corpului progestativ ovarian, astfel încât blastocistul ajunge până în regiunea istmică şi se implantează la acest nivel. Implicarea miometrială este, de asemenea, în studiu, un aspect la care ne referim şi noi (7,8).

MATERIAL ŞI METODĂ

În studiu, am inclus 53 (3,84%) cazuri de *placenta praevia*, din totalul pacientelor asistate în Spitalul Clinic de Obstetrică şi Ginecologie "Cuza Vodă" Iaşi în perioada 2006-2009.

Culegerea datelor s-a realizat prin analiza foilor de observaţie, urmărind: incidenţa pe grupuri de vârstă, motivele internării, paritatea, antecedentele obstetricale patologice, istoricul sarcinii, simptomele de debut, rezultatele examenului obiectiv, programul terapeutic şi starea nou-născutului.

REZULTATE ŞI DISCUŢII

1. Relaţia dintre vârstă, paritate şi prezenţa placentei praevia. Deşi în toate grupu-

TABELUL I

Distribuţia pe grupuri de vârstă a cazurilor cu *placenta praevia*

Vârsta (ani)	Nr. cazuri	%*)
16-20	1	1,89
21-25	11	20,75
26-30	17	32,08
31-35	7	13,21
36-40	9	16,98
peste 41	8	15,09
Total	**53**	**100,00**

*) pentru valorile mai mici de 10, proporţiile sunt orientative

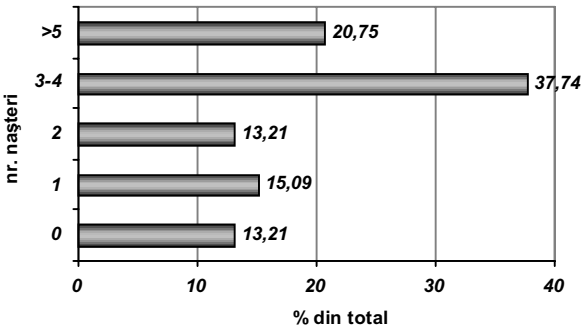

Fig. 1. Incidenţa *placentei praevia* pe grupuri de paritate

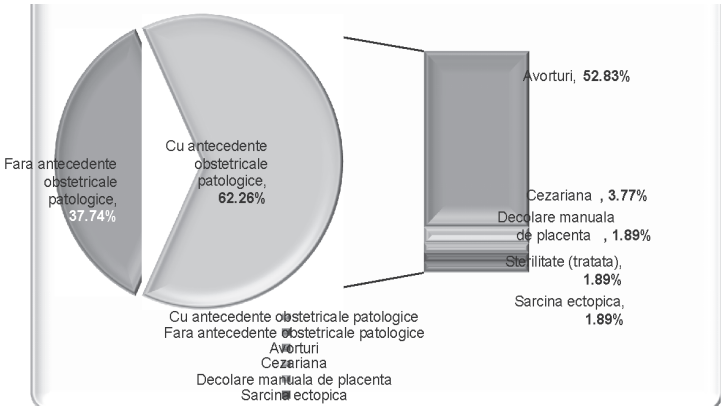

Fig. 2. Prevalenţa antecedentelor obstetricale patologice

rile de vârstă s-au înregistrat cazuri de *placenta praevia*, cele mai frecvente (52,83%) au fost semnalate în intervalul demografic 21-30 ani (tab. I).

În funcţie de paritate, cazurile au prezentat o distribuţie neomogenă, evidenţiind o incidenţă care creşte odată cu cea a parităţii : secundipare – 13,2% ; terţipare – 20,75% şi 37,7% - multipare, dar la primipare, incidenţa a fost mai scăzută (13,21%) (fig. 1).

2. Antecedentele obstetricale ale cazurilor incluse în studiu. S-au înregistrat 18 gravide cu 1-2 avorturi (33,96%) şi 10 peste 2 avorturi (18,86%) ; 2 cazuri cu cezariană, 1 caz cu două manevre de decolare manuală de placentă, 1 caz cu sarcină ectopică şi 1 cu tratament pentru sterilitate. Deci, din cele 53 gravide cu *placenta praevia*, 33 (62,26%) au prezentat un trecut obstetrical patologic (fig. 2).

3. Relaţia dintre momentul debutului afecţiunii şi evidenţierea manifestărilor clinice. În cercetările unor autori (2,3,5) s-a menţionat că manifestările clinice în cazul *placenta praevia* apar în luna a 8-a (40%) şi în ultima lună (30%), restul distribuindu-se uniform în lunile 5, 6 şi 7. În cazul nostru, debutul a fost cel mai frecvent în luna a 8-a, urmată îndeaproape de a 9-a, iar cu valori mult mai mici, au fost lunile 6 şi 7 şi cel mai puţin, luna a 5-a (fig. 3).

4. Unele caracteristici ale debutului. Noi am constatat că acesta este reprezentat de cele mai multe ori de hemoragie (77,35%) şi, în măsură mult mai mică, de ruptura prematură a membranelor (15,09%) şi imi-

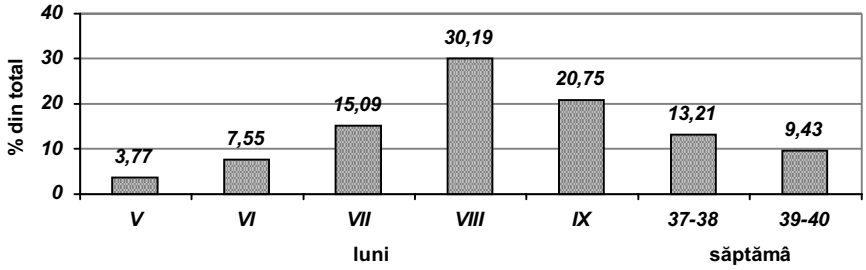

Fig. 3. Momentul debutului afecţiunii

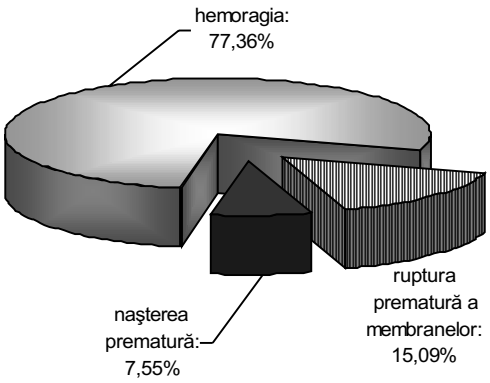

Fig. 4. Simptomatologia principală de debut

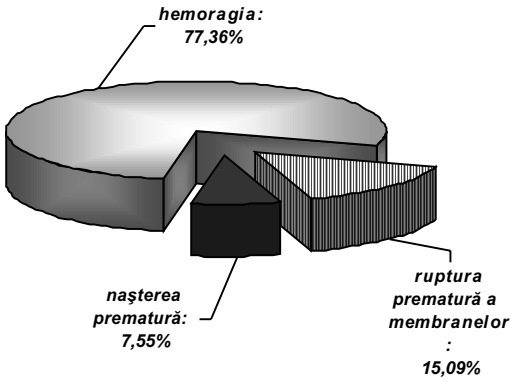

Fig. 5. Aspecte privind structura manevrelor terapeutice

nenţă de naştere prematură (7,54%).

Datele noastre concordă cu cele obţinute de alţi autori (1,2,8,9), care susţin că simptomul de debut este reprezentat, îndeosebi, de hemoragie (70%), urmată de ruptura prematură a membranelor (15%), iar în rest fiind vorba de asocieri ale celor două manifestări (fig. 4).

5. Studii histopatologice. Debutul, cel mai frecvent, a fost hemoragic, ceea ce presupune apariţia unor modificări miometriale, motiv pentru care s-au realizat investigaţii histopatologice, pentru a sublinia tipul reacţiei miometriale.

În cazurile cu absenţa parţială sau totală a *deciduei* bazale şi dezvoltarea imperfectă a stratului de fibrinoid, a determinat favorizarea contactului direct între vilozităţi şi miometru (*accreta*), urmat de invazia miometrului (*increta*) şi traversarea miometrului (*percreta*).

Studiul a evidenţiat că, la nivelul miometrului, au fost prezente toate cele trei tipuri caracteristice de joncţiuni ale fibrei musculare netede, respectiv caveolele, zonele asherens şi joncţiunile digitiforme, dar mult modificate ca repartiţie şi număr. În aceste condiţii, un număr redus de joncţiuni determină ca masa musculară uterină să nu mai poată atinge pragul de contracţie necesar atât opririi hemoragiei prezente în sarcina cu *placenta praevia*, cât şi desfăşurării unui travaliu normal. Concomitent, este necesar a fi luat în consideraţie şi rolul oxitocinei în susţinerea contracţiei musculare uterine (3,5,).

6. Aspecte ale eficienţei terapeutice. Studiul a arătat că tratamentul aplicat gravidelor a fost diferit în relaţie cu vârsta sarcinii, starea mamei şi a fătului, valoarea socială a viitorului născut. Astfel, 35 (66,37%) gravide au beneficiat de un tratament medical, pentru 8 (15,09%) cazuri s-a efectuat cezariană de urgenţă, iar 10 (18,86%) au

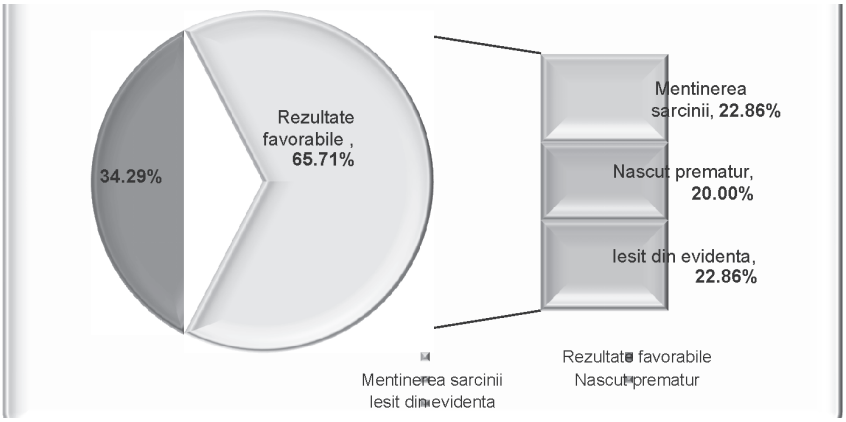

Fig. 6. Rezultatul tratamentului medical

TABELUL II

Parametrii biostatistici estimaţi privind asocierea evoluţia cazurilor cu *placenta praevia* supuse tratamentul medical

(df=1)	Chi-pătrat χ^2	p (*95% interval de încredere*)
M-L Chi-pătrat - χ^2	5,16	0,0231777
Coeficient de corelație (Spearman Rank R)	0,68	0,0359378

TABELUL III

Estimarea parametrilor de şansă şi risc ale evoluţiei cazurilor cu *placenta praevia* care au beneficiat de tratament medical

Parametri	Valoarea estimată	95% interval de încredere	
		min.	max.
Raportul şansei (OR)	2,24	1,05	4,83
Riscul relativ (RR)	2,17	1,09	4,30

născut pe cale naturală (fig. 5).

Dintre gravidele cu *placenta praevia*, tratamentul medical a reuşit în 8 cazuri, cu menţinerea sarcinii până la 39-40 săptămâni, necesitând internări repetate, iar 20% au născut prematur (9, 10) (fig. 6).

7. Analiza statistică a dovedit că tratamentul medical al pacientelor cu *placenta praevia* are şanse semnificative pentru o evoluţie favorabilă ($\chi^2=5,16$; $p=0,0231$; 95% CI) (tab. II).

S-a constatat că tratamentul medical în cazurile cu *placenta praevia* are şanse de 2,24 ori mai mari pentru o evoluţie favorabilă (OR=2,24), dovedind că raportul de risc reprezintă un indicator prospectiv privind eficienţa tratamentului medical, care induce o evoluţie favorabilă a sarcinii (tab. III).

CONCLUZII

Progresele obţinute în stabilirea diagnosticului de *placenta praevia*, cu explorare ecografică de rutină, cu o supraveghere susţinută a gravidelor cu sângerare îndeosebi în trimestrul al III-lea de sarcină şi datorită promovării naşterii prin cezariană, a determinat scăderea mortalităţii materne. Pentru sarcina cu *placenta praevia*, naşterea prematură continuă a reprezenta riscul major.

Investigaţiile histopatologice în *placenta praevia* s-au dovedit utile pentru cunoaşterea factorilor de risc, detectarea fenomenelor de acretizare, stabilirea concordanţei cu examenul imagistic, anticiparea evoluţiei şi promptitudinea aplicării conduitei terapeutice şi, în final, ameliorarea prognosticului.

MULTI-STAGED ENDOVASCULAR SOLUTION FOR A COMPLEX, GIANT VERTEBRAL-BASILAR JUNCTION ANEURYSM (Abstract): We present a very particular case of a complex vertebral-basilar junction aneurysm in a 34-year-old male patient. The patient benefited from a multi-stage endovascular treatment with a good neurological result at 12 months follow-up. Following an intricate history and a complex diagnosis process, we describe the therapeutic challenges and the steps taken in securing the aneurysm and dealing with the complicated hemodynamic architecture of the aneurysm and vertebral-basilar complex as well as the critical neurological evolution during the multi-staged process. Our case brings a new perspective to a rare and very difficult pathology and contributes to an increasing pool of data regarding the clinical management and the therapeutic options in this type of vascular lesions. **Keywords**: COMPLEX, VERTEBRAL-BASILAR, ANEURYSM, ENDOVASCULAR, TREATMENT

Vertebral-basilar junction giant aneurysms are rare and raise big challenges in terms of management and outcome. We present a case, which was particularly challenging in terms of management not described previously in the literature (1-4). We describe the approach to secure the aneurysm and the imagistic and clinical outcome.

CASE REPORT

The history of the 34-year-old male patient started 3 months prior to presentation in our service with persistent headache and vertigo. Two months later his condition worsened with right side progressive hemiparesis (a deficit score MRC 3/5) accompanied by mild dysphonia and dysphagia. Patient was admitted to a local medical emergency unit where the CT scan (fig. 1 A) showed a well delineated hyperdense mass in the posterior fossa, anterior to the medulla. He received symptomatic treatment and was referred to a specialized neurovascular department. Two weeks later it experienced the first syncope, which determined his presentation to a neurovascular unit where the MRI (fig. 1 B, C) confirmed a giant unrupted vertebro-basilar aneurysm.

The diagnostic angiography performed afterwards defined the aneurysm anatomy and its hemodynamics (fig. 1 D, E, F). Considering the fact that the aneurysm had quite large dimensions the choice of treatment method was not easy. Must be considered

the fact that the symptoms were determined by mass effect on the medulla or the cerebral micro emboli. We decided that, given the localization and the vascular anatomy of the aneurysm, the best way to approach is a multi-stage endovascular treatment.

The first step was a balloon occlusion test of the left vertebral artery (fig. 1 G) with the patient awake. The main reason for this test was the absence of a dominant posterior communicant artery. 10 minutes occlusion resulted in no changes in clinical status. As a result, we decided to permanently occlude the artery which we achieved by coiling PICA close to its origin.

The procedure was performed under general anesthesia with systemic heparinization for the whole duration. We performed the procedure with a 6F introducer and selective catheterization of the left vertebral artery through a 6F Mach 1 guiding catheter on a 0.035" hydrophilic guidewire. We then performed microcatheterization of the left vertebral artery in the neighborhood of PICA at the skull entry with Excelsior SL-10 microcatheter on a 0.014 micro guidewire. 5 GDC-10 coils were introduced and detached until complete vertebral artery occlusion was achieved (fig. 1 H, I). We verified angiographically the patency of the left PICA. We observed a significant difference in the pattern of aneurysm filling as it changed from unidirectional concurrent flow to a circular flow running on the entire surface of the aneurysm wall figure 1 J, compare to figure 1 E.

At 24 hours after the intervention, the patient showed a slight deterioration of the initial symptoms with onset of dyspnea, followed by desaturation and obnubilation, and he was intubated. The control CT showed a mild increase of the aneurysm volume. In this context, we decided to postpone the second procedure after clinical stabilization. One-month post-procedure the patient showed reliable signs of stabilization from a clinical point of view.

The second procedure consisted in a quasi-total spiral embolization of the aneurysm secured with stent, under general anesthesia and heparinization for the whole duration (5000 IU/hr). Double antiaggregating (Fraxiparine 0.6 mg/12 hrs and Aspenter 150 mg/day) was initiated one week prior to the procedure. The same approach was performed on a 6F introducer. Vertebral artery was selectively catheterized using a 6F catheter on a 0.0035 hydrophile guide. Passing a micro-guide from the vertebral artery to the basilar trunk was difficult due to the circular flow in the aneurysmal sac. We managed to pass a 0.010 Transcend micro-guide which was followed by a stent carrying catheter (4.5/50 mm Self-Expandable LEO+). Stent detachment was initiated in the middle part of the basilar trunk to the entry point of the vertebral artery into the aneurysm. With the stent partially detached, we catheterized the aneurysm with an Excelsior SL-10 microcatheter on a 0.014 guidewire. 8 GDC® 360° detachable coils (sizes from 15/30 mm to 6/11 mm) were placed and detached until partial occlusion of the aneurysmal sac. Finally, the spiral delivery catheter was pulled back and the detachment of the stent was finalized (fig. 1 L, M).

The CT, MRI, and Angio-MRI controls at 14 days showed partial thrombosis of the aneurysmal sac, vascular patency within the stent, and an overall reduction in aneurysm volume. At one-year follow-up MRI and angiography showed a stable evolution of the aneurysm and endovascular implants (fig. 1. N, O) but not a significant clinical improvement compared to the discharge status.

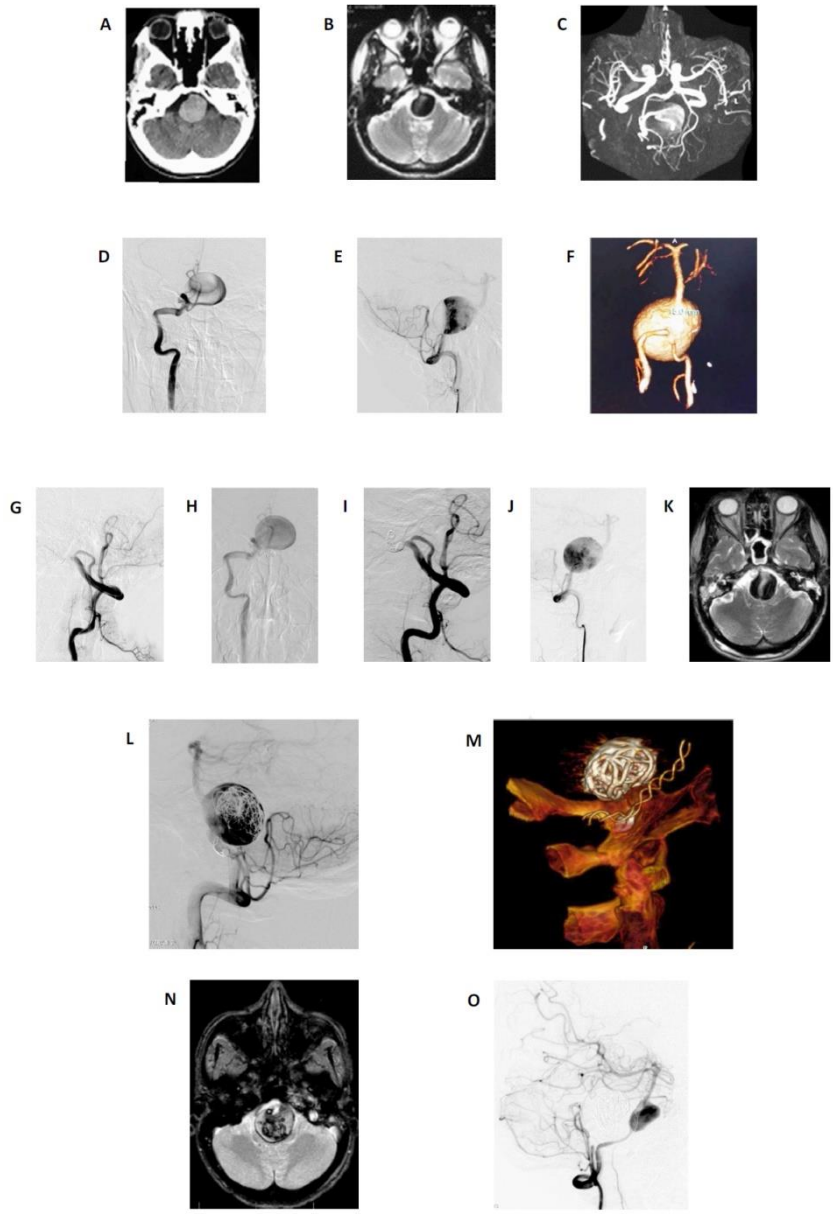

Fig. 1. A) Initial CT, B-C) Initial T2 weighted MRI with Angio-MRI, D-F) diagnostic angiography, showing the flux (D), aneurysm filling pattern (E), and 3D reconstruction with dimensions (F), G) Angiography during balloon occlusion, H) Flux in the aneurysm after left vertebral artery occlusion, I) Detail showing the patency of PICA, J) Aneurysm filling after left vertebral artery occlusion, K) MRI control after vertebral occlusion, L) Final angiographic image after aneurysm coiling and stent placement, M) 3D reconstruction of the endovascular construction, N) MRI at 5 months follow-up, O) Angiography at 5 months follow-up.

DISCUSSION

The giant vertebro-basilar trunk aneurysms are rare and very difficult cases due to their location, complex vascular anatomy, and very intricate hemodynamics. In the case presented, during the angiography, is very well illustrated the turbulent flow at the level of the aneurysm sac. The main vascular flow into the aneurysm is from the right vertebral artery and to a very small extent form the left vertebral artery. For this reason, the decision was reached that closing the left vertebral artery will reduce the flow into the aneurysm.

The wide-necked aneurysms are more effectively treated with stent-assisted coiling. Following the hemodynamic changes manifest after left vertebral artery occlusion, with important changes in the aneurysmal flow, the increase of aneurysm wall pressure and worsening of the clinical status because of brainstem compression, we reasoned that we have to use the technique that will increase the chances of a slow aneurysm thrombus formation.

The first requirement for the stent was to have enough radial force to allow a coil construction with a support from the aneurysmal wall of about 1/3 of the circumference. In addition, the presence of numerous perforator arteries originating from the portion of the aneurysmal wall that supported the stent required a stent of medium porosity (5).

The decision to use a LEO plus stent (and not a laser-cut stent or a flow-diverter) in the treatment of this vascular lesion was based on a number of factors. The LEO Plus stent (Balt) has a design that offers a higher radial force compared to flow diverters (6, 7). We believed that is was needed to insure a better support of the coil's construction. Another particularity is that the LEO (+)'s cells are closed but not predetermined in size and shape and allow for an easier access of a microcatheter for an eventual subsequent recoiling (8). It is also known that the maximal differential pressure inside the aneurysm remains high for high porosity stents (5), which implies that the flow reduction inside the aneurysm is not enough. A more suited pressure could be achieved using LEO+ stent that offers larger cells than flow diverters with less hemodynamic effect on the aneurysm and thus a slower thrombosis (8).

CONCLUSIONS

We present a very particular case that benefited from a multi-stage, complex endovascular treatment with a good result at 12 months' follow-up.

Our case brings a new perspective to a rare and very difficult pathology and contributes to an increasing pool of data regarding this type of aneurysms.

NEWS

IT'S ALL IN THE EYES: ASSOCIATION BETWEEN RETINAL NERVE FIBER LAYER THICKNESS AND RISK OF COGNITIVE DECLINE

The global burden of people with neurodegenerative pathology is increasing and this is why there is a great desire to discover the perfect screening tool for cognitive decline. A group of researchers used the retina as "mirror image" of the central nervous system and conducted a study on 32,038 UK residents aged 40 to 69 who underwent cognitive testing and optical coherence tomography imaging. They discovered that participants with a thinner retinal nerve fiber layer (RNFL) were more likely to fail at least 1 or more of the 4 cognitive tests compared to those who had a RNFL of at least 60.2 μm. Furthermore, a repeated assessment of 1251 participants after 3 years showed that those with a thinner baseline RNFL did worse on at least 1 follow up cognitive test. This is a very exciting study because it opens new directions for research in the prevention and treatment of dementia and it is the largest one of this kind so far. (Ko F, Muthy ZA, Gallacher J, *et al.* Association of Retinal Nerve Fiber Layer Thinning with Current and Future Cognitive Decline: A Study Using Optical Coherence Tomography. *JAMA Neurol*. 2018; 75(10): 1198-1205).

FUNGI AS ETIOLOGIC EMERGENT AGENTS OF THE VENTILATOR-ASSOCIATED PNEUMONIA AFTER CARDIAC SURGERY (Abstract): Evaluation of the fungal involvement in the etiology of ventilator-associated pneumonia (VAP) after cardiac surgery. The study had as target the patients diagnosed with VAP after cardiac surgery at the Institute of Cardiovascular Diseases in Iaşi, between April 2nd 2002 and December 31st 2009. **Material and method**: Our study included only cases with fungal etiology of VAP. We examined quantitatively the tracheal aspirates with cytology quality score Q = 2+: microscopy and cultivation. The isolates with clinical significance (= 10^6 UFC/mL significantly associated to inflammatory cells) were identified by standard methods or based on the API system (bioMérieux) and tested by the breakpoints method for susceptibility to antifungal agents. **Results**: Among the 2167 operated patients, 35 of them were diagnosed with VAP through the clinical pulmonary infection score = 6. Fungi caused 15 of 44 VAP episodes. With a frequency of 30.19%, fungi are on 2nd place within the etiologic agents of VAP after non-fermenting Gram-negative bacilli (45.28%). The fungi involved in VAP were: *Candida albicans* (16,97%), *Pneumocystis jirovecii* (3.77%), while *Candida glabrata*, *Candida sake*, *Candida krusei*, *Geotrichum capitatum* and *Cryptococcus humicola,* amounted 1.89% each. The widespread use of broad spectrum antibiotics led to the emergence of fungi as a common cause of ventilator-associated pneumonia. The involvement in the VAP etiology of *P. jirovecii*, an un-cultivable fungus with special sensitivity to antibiotics, requires a careful microscopy of specimens. **Key words**: ETIOLOGY, FUNGI, VENTILATOR-ASSOCIATED PNEUMONIA, CARDIAC SURGERY

Pneumonia asociată ventilaţiei mecanice (PAV) este cea mai frecventă infecţie nosocomială din unitatea de terapie intensivă (UTI) post chirurgie cardiacă, cu mortalitate de 16-76% (1,2,3).

Agenţii etiologici comuni ai PAV sunt: *Pseudomonas* spp., stafilococi, *Enterobacteriaceae, Acinetobacter* spp., alte specii de bacili gram-negativi multirezistenţi la antibiotice, streptococi şi *Haemophylus* spp. Fungii sunt potenţiali agenţi patogeni ai PAV, dar nu au fost consideraţi comuni în contextul pneumoniei apărute pe perioada ventilaţiei mecanice (VM) (1,4).

Scopul acestui studiu a fost evaluarea implicării fungice în etiologia PAV la pacienţii din UTI post chirurgie cardiacă la Institutul de Boli Cardiovasculare din Iaşi (IBCVI).

TABELUL I
Etiologia PAV în perioada 02.04.2002 - 31.12.2009

Microorganisme	Număr	%
Pseudomonas aeruginosa	10	18,87
Acinetobacter baumannii	9	16,97

MATERIAL ŞI METODĂ

Am analizat retrospectiv pacienţii diagnosticaţi cu PAV în UTI aferentă secţiei de chirurgie cardiovasculară (CCV) la IBCVI în perioada 02.04.2002-31.12.2009. Eligibili au fost pacienţii operaţi pe cord sau vasele mari, cu vârsta ≥ 14 ani, cu VM ≥ 48 ore şi PAV cu etiologie fungică. Această unitate are 12 paturi cu un rulaj mediu anual de 53,95 pacienţi per pat. Studiul a fost aprobat de Comisia de Etică a IBCVI.

Exsudatele căilor respiratorii inferioare au fost prelevate cu ajutorul unei sonde de aspiraţie (lungimea = 50 cm, mărimea 14 Fr) introdusă prin tubul endotraheal, iar secreţiile au fost aspirate fără instilare de soluţie salină. Aspiratele traheale cu scorul citologic de calitate Q ≥ 2+ le-am examinat cantitativ prin citobacterioscopie (frotiuri colorate Gram, eventual Giemsa) şi izolare prin epuizarea diluţiilor 10^{-2} şi 10^{-3} pe medii agarizate (geloză-sânge, agar Mac Conkey, agar Sabouraud cu cloramfenicol) (5). Incubarea a fost aerobă cu citirea culturilor la 24, 48 ore, iar pentru fungi până la 7 zile. Am identificat izolatele prin metode standard şi sistemul automat API pe galerii ID32 C (bioMérieux) şi le-am testat sensibilitatea la antifungice prin metoda punctelor de ruptură pe galerii ATB Fungus 3 (mini API - bioMérieux).

DEFINIŢII

Pneumonia asociată VM a fost diagnosticată prin scorul clinic de infecţiozitate pulmonară (SCIP) ≥ 6. Calcularea acestui scor include 7 variabile: temperatura (≥ 38,5°C/< 36°C), numărul de leucocite (< 4000/> 11000 leucocite/mmc), oxigenarea pulmonară apreciată prin raportul dintre presiunea parţială a oxigenului arterial şi fracţia inspiratorie a oxigenului (PaO2/FiO2), aspectul şi progresia infiltratului pulmonar pe radiografia toracică (Rx), aspectul şi cultura aspiratului traheal (6). Prezenţa unui infiltrat pulmonar nou şi/sau progresiv pe Rx a fost obligatorie (7). PAV este clasificată *precoce* sau *tardivă* în raport cu debutul, = 4, respectiv > 4 zile de VM (1).

Traheobronşita asociată VM (TAV) a fost definită de absenţa leziunilor evolutive de pneumonie pe Rx în prezenţa aspiratelor traheale purulente, febrei şi leucocitozei (7).

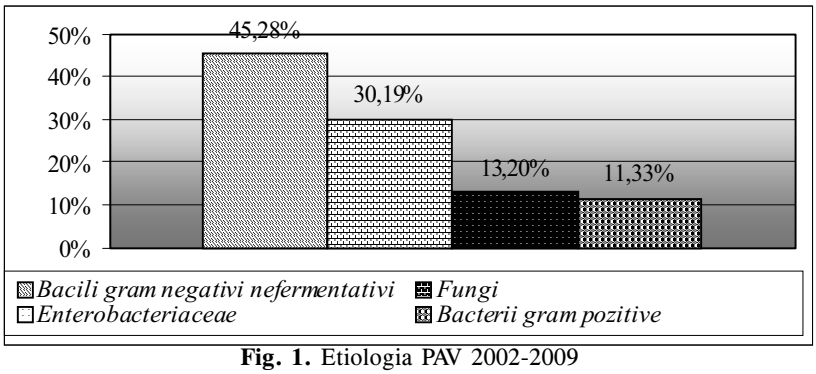

Fig. 1. Etiologia PAV 2002-2009

Cazurile de PAV sau TAV au fost confirmate microbiologic (5) când : fungii izolaţi în cantităţi ≥ 10^6 UFC/mL s-au regăsit semnificativ asociaţi celulelor inflamatorii pe frotiul Gram din aspiratul traheal ; acelaşi izolat din aspiratul traheal a fost regăsit şi în hemocultură ; chişti şi/sau forme trofice ale *Pneumocystis jirovecii* (fung necultivabil) au fost observaţi pe frotiurile colorate Giemsa ale aspiratelor traheale (5).

Colonizarea tractusului respirator inferior : prezenţa unui microorganism în cultura aspiratului traheal în absenţa semnelor clinice de infecţie a tractusului respirator inferior şi asociaţiei semnificative cu celulele inflamatorii (5).

Doze zilnice prescrise (DZP) reprezintă frecvenţa cumulată a dozelor zilnice de agenţi antimicrobieni prescrişi după natura acestora.

Un episod de PAV reprezintă debutul unei pneumonii urmat sau nu de vindecare clinică şi microbiologică la un pacient intubat ≥ 48 de ore.

Ventilaţia mecanică prelungită este VM cu o durată mai mare de 48 de ore la un pacient intubat (1).

REZULTATE

Pe parcursul celor 7 ani de studiu au fost operaţi 2167 pacienţi. Postoperator, 40 au fost suspectaţi de PAV : 35 confirmaţi cu PAV, iar 5 cu TAV. Cei 35 de pacienţi au avut 44 episoade de PAV în care au fost implicate 53 de microorganisme (tab. I). Toţi pacienţii au avut VM prelungită.

Cinsprezece pacienţi (42,86%) din 35 au avut 15 episoade de PAV cu fungi, care au fost : monomicrobiene 10 (66,67%), posibil mixte 5 (33,33%). Acestea au fost asocieri ale fungilor cu o bacterie (*C. albicans* cu *A. baumannii*, cu *E. aerogenes* sau cu *C. striatum/amycolatum* ; *C. glabrata* cu *E. coli*) sau cu alt fung (*P. jirovecii* cu *C. krusei*). Ca debut, cele 15 episoade de PAV au fost : 7 precoce (46,67%) şi 8 tardive (53,33%).

Din 15 pacienţi 10 (66,67%) au avut mai mult de 60 de ani. Dintre comorbidităţi, insuficienţa cardiacă (IC) definită prin criteriile *New York Heart Association* (NYHA) şi clasificată în 4 grade (I, II, III şi IV) a fost prezentă la toţi (33,33% – II ; 46,67% – III ; 20% – IV). Diabet zaharat (DZ) au avut 4 (26,67%), iar 3 (20%) au prezentat boli pulmonare cronice. Intervenţia s-a efectuat cu utilizarea circulaţiei extracorporeale (CEC) la 14 (93,34%) din cei 15 pacienţi. Apariţia PAV a fost precedată în 5 cazuri (33,33%) de : colonizare 1 (6,66%) şi traheobronşită 4 (26,67%). Hemoculturi pozitive cu acelaşi fung izolat din aspiratul traheal au avut 2 (13,34%) dintre pacienţi.

Cei 15 pacienţi au primit antibiotice (214 DZP) : preoperator, 3 pacienţi (20%) au primit terapie antimicrobiană : unul ceftriaxonă (11 DZP), altul ciprofloxacin (5 DZP),

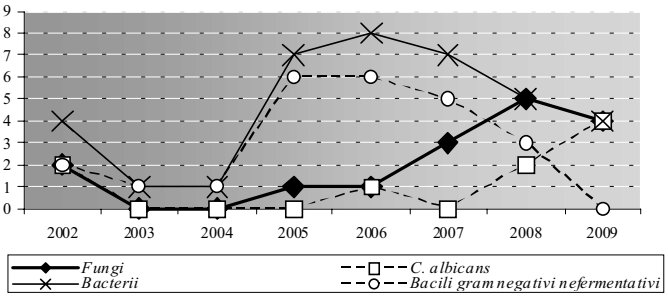

Fig. 2. Prevalenţa microorganismelor în etiologia PAV 2002 - 2009

iar ultimul ampicilină (9 DZP); intraoperator şi postoperator, toţi pacienţii au primit antibiotice până la episodul de PAV (189 DZP) şi toţi au primit antibiotice cu spectru larg.

Din totalul de 214 DZP administrate la pacienţi (preoperator, intraoperator şi postoperator), cele mai frecvente au fost antibiotice cu spectru larg, respectiv 148 DZP (69,16%): cefalosporine de generaţia a III-a 43,93%, fluoroquinolone 18,22% şi imipenem 7,01%.

Cu o frecvenţă de 30,19% fungii ocupă locul 2 între agenţii etiologici ai PAV după bacilii gram negativi nefermentativi (45,28%) (fig. 1). Şaisprezece fungi au fost implicaţi în PAV: 9 *C. albicans* (16,97%), 2 *P. jirovecii* (3,77%) şi câte o tulpină de *C. glabrata*, *C. sake*, *C. krusei*, *G. capitatum* şi *C. humicola* fiecare cu frecvenţa de 1,89% (tab. I).

Prevalenţa implicării fungice în etiologia PAV a crescut în perioada 2002 - 2009 de la 2 la 4 izolate, cu un maxim de 5 izolate în 2008. *C. albicans* a fost cel mai frecvent patogen al PAV în 2009. După ce bacilii gram negativi nefermentativi au fost cei mai frecvenţi agenţi etiologici ai PAV timp de 3 ani (2005 - 2007), cu un maxim de 6 izolate în anii 2005 şi 2006, în 2008 am izolat 3, iar în 2009 au fost absenţi (fig. 2).

DISCUŢII

Microorganismele implicate în etiologia PAV sunt variate. Fiecare UTI are un spectru etiologic propriu. Factorii de risc care favorizează apariţia PAV şi-i influenţează spectrul etiologic pot fi grupaţi în 4 categorii: 1) condiţii care predispun la o creştere a colonizării orofaringelui şi/sau stomacului cu microorganisme (agenţii antimicrobieni, internarea în UTI, prezenţa bolilor pulmonare cronice); 2) factori care favorizează aspiraţia în tractul respirator inferior a secreţiilor orofaringiene sau refluate din tractul digestiv (intubaţia endotraheală, intervenţii chirurgicale toracice şi la nivelul abdomenului superior); 3) situaţii care necesită utilizarea prelungită a VM; şi 4) factori proprii gazdei – vârsta înaintată (> 60 de ani), imunosupresia (8, 9).

Park (4) într-un studiu din 2005 privind etiologia PAV la pacienţi imunocompetenţi din diferite UTI (medicale, chirurgicale, medico-chirurgicale, secţii de traumatologie) au stabilit că patogenii comuni nu includ fungii, dar la pacienţii imunosupresaţi devin cauze importante.

Ashman et al, în 2004 (10) au studiat răspunsul imun în infecţiile fungice: principalul mecanism de apărare este mediat celular de limfocitele T şi o deficienţă a acestui sistem predispune la infecţii invazive cu fungi (*Candida albicans*). Pacienţi imunodeprimaţi sunt şi cei cu boli cronice (DZ, IC) (9). Chirurgia cardiacă cu CEC determină o scădere a imunităţii mediată de limfocitele T. Funcţiile limfocitelor T sunt supresate sever din ziua 1 post-operator cu revenire la valorile preoperatorii în zilele

3-5 după intervenţie (11). Aceste modificări sunt responsabile de scăderea competenţei răspunsului imun nespecific şi specific la pacienţii supuşi chirurgiei cardiace cu CEC (12). Astfel, am putea considera pacienţii post chirurgie cardiacă un grup de pacienţi aparte, cu o supresie temporară a imunităţii.

Studiul nostru a vizat o subpopulaţie de pacienţi, a celor supuşi intervenţiilor cardiace : la majoritatea s-a folosit CEC (93,34%) şi toţi au avut IC (100%). Aceste date ar explica apariţia precoce a PAV fungică (46,67%).

În studiul nostru fungii au ocupat locul 2 după bacilii gram negativi nefermentativi. *C. albicans* a fost cel mai frecvent fung şi a ocupat locul 2 după *P. aeruginosa* (18,87%), pe acelaşi loc cu *A. baumannii* (16,97%) în etiologia PAV. Fungii, în primul rând *C. albicans* au devenit agenţi etiologici comuni ai PAV la IBCVI.

Datele obţinute de noi cu privire la etiologia PAV se corelează cu cele obţinute de Wójkowska et al (13) în 2009 : cei mai comuni agenţi etiologici ai PAV după chirurgie coronariană sunt bacilii gram negativi şi fungii : *K. pneumoniae* 16,7%, *C. albicans* 14,6%, *E. coli* 12,5% şi *P.aeruginosa* 10,4%.

Presiunea selectivă a medicaţiei antimicrobiene are un rol major în selectarea tulpinilor şi speciilor cu rezistenţă intrinsecă (fungi) (1).

Adăugarea presiunii selective a terapiei antimicrobiene (aproximativ 70% cu spectru larg – cefalosporine de generaţia a III-a, fluoroquinolone, carbapeneme) la factorii ce determină imunosupresie în grupul nostru de pacienţi (IC – 100%, DZ – 26,67%) explică apariţia tardivă a PAV cu etiologie fungică (53,33%).

El-Ebiary et al. (14) într-un studiu cu privire la semnificaţia izolatelor de *Candida* spp. din exsudatele tractusului respirator inferior la pacienţi critici fără neutropenie constată că deşi izolarea acestora este frecventă, ele reprezintă mai degrabă colonizări decât pneumonii la pacienţii imunocompetenţi. Toţi pacienţii noştri au avut un anumit grad de imunosupresie prin bolile preexistente (IC – 100%, DZ – 26,67%) (9).

Datele din literatură (1, 4, 5, 15) recomandă o interpretare prudentă a semnificaţiei clinice a speciilor de *Candida* izolate din aspiratele traheale ale pacienţilor imunocompetenţi cu suport ventilator mecanic. Biopsia pulmonară cu evidenţierea fungilor şi/sau pseudohifelor este metoda care poate confirma implicarea *Candida* spp. în etiologia PAV. Hemoculturile pozitive, exsudatul pleural cu acelaşi izolat din aspiratul traheal confirmă etiologia PAV (5, 15). La pacienţii studiaţi de noi nu s-a efectuat biopsie pulmonară, nu am avut exsudate pleurale, iar hemoculturile au fost pozitive cu aceeaşi tulpină de *Candida* la 2 (13,34%) din cazuri.

Implicarea *P. jirovecii* (fung necultivabil) în etiologia PAV post chirurgie cardiacă la IBCVI impune o microscopie atentă (frotiuri colorate Gram, Giemsa) a prelevatelor la pacienţii cu scădere persistentă a saturaţiei arteriale a oxigenului, fără răspuns la antibiotice cu spectru larg şi cu imagini radiologice „aproximativ normale". Se recomandă terapie cu trimetoprim-sulfametoxazol, per os/intravenos, 15-20/75-100 mg/kgc/zi pentru 14 zile (16).

CONCLUZII

1. Emergenţa fungilor drept cauză comună a pneumoniei asociată ventilaţiei mecanice în unitatea de terapie intensivă post chirurgie cardiacă la IBCVI se datorează unui cumul de factori : pacienţii prezintă insuficienţă cardiacă, ceea ce le conferă un grad de *imunodepresie* ; pacienţii post chirurgie cardiacă la care s-a folosit CEC prezintă o *imunosupresie temporară* din ziua 1 până în zilele 3-5 postoperator ; şi utilizarea pe scară largă a antibioticelor cu spectru larg (cefalosporine de generaţia a III-a, carbapeneme, fluoroquinolone) care afectează bariera

ecologică a pacienţilor.
2. Semnificaţia clinică a izolatelor fungice (*Candida* spp.) trebuie interpretată cu prudenţă pentru fiecare caz.
3. Implicarea în etiologia PAV a *P.jirovecii*, fung necultivabil cu sensibilitate aparte la antibiotice, impune microscopia atentă a prelevatelor.

IN VITRO EVALUATION OF NOVEL FUNCTIONALIZED NANOPARTICLES FOR TERAHERTZ IMAGING (Abstract): **Background**: Early clinical diagnosis of gastric cancer is crucial for the treatment of patients, with increased healing rates being achieved by digestive endoscopy or surgery in patients with early gastric cancer. Magnetic nanoparticles (MNPs) are a major class of nanoscale materials currently under extensive development for improved diagnosis of a wide range of diseases, including cancer, cardiovascular disease and neurological disease. The nanoscale dimensions of MNPs give rise to unique magnetic properties and the ability to function on a cellular and molecular level, these characteristics making MNPs such promising contrast agents in different imaging applications. **Aim:** The research was focused on the development of some new nanoparticles suitable for use as contrast agents for terahertz imaging and assessment of the impact on gastric cell line AGS viability. **Material and methods:** Magnetite/Fe_3O_4 and Gd_2O_3 were functionalized by citric acid and carboxymethylcellulose and were tested on the standardized human gastric cell line AGS for the impact on cell viability by MTT assay. **Results**: Fe_3O_4 nanoparticles have induced a smaller amount of cytotoxicity at the first two dilutions, followed by an increase of the cytotoxic effect with the maxim effect at the dilution of 1:1. Also, the Gd_2O_3 stabilized in carboxymethylcellulose has presented a moderate cytotoxic impact in the range of 1:75 to 1:5 dilutions, followed by registration of a significant toxic effect at 1:1 dilution. **Conclusions**: The results obtained indicate that there is a high degree of tolerance to the tested nanoparticles, pointing out these nanoparticles suitable as contrast agents. **Keywords:** FUNCTIONALIZED NANOPARTICLES, TERAHERTZ IMAGING, AGS CELL LINE, IN VITRO CYTOTOXICITY.

Cancer is a common disease, with a high impact on mortality and the quality of life, and also with psychological and health budget impact. Due to its long asymptomatic character cancer is poorly recognized in the early stages of its development (1).

Among the most common causes of cancer death in the world it is also the gastric cancer (with approximately 738,000 deaths per year, accounting for about 9.7% of all

cancers) (2). Early clinical diagnosis of gastric cancer is crucial for the treatment of patients, with increased healing rates being achieved by digestive endoscopy or surgery in patients with early gastric cancer.

Iron oxides are natural compounds, often find in natural conditions, and easy to synthesized in laboratory conditions. Iron oxide nanoparticles consist of maghemite (γ-Fe_2O_3) and/or magnetite (Fe_3O_4) particles with diameters ranging from 1 and 100 nanometer and find applications in magnetic data storage, biosensing, drug-delivery etc.

Nanotechnology has given scientists new tools for the development of advanced materials for the detection and diagnosis of disease. Magnetic nanoparticles (MNPs) are a major class of nanoscale materials currently under extensive development for improved diagnosis of a wide range of diseases, including cancer, cardiovascular disease and neurological disease. The nanoscale dimensions of MNPs give rise to unique magnetic properties and the ability to function on a cellular and molecular level. It is the combination of these characteristics that make MNPs such promising contrast agents in different imaging applications (3). Among the various MNPs under investigation, superparamagnetic iron oxide nanoparticles (SPIONs) have attracted considerable interest due to their excellent magnetic properties, biocompatibility and biodegradability.

Iron oxide nanoparticles tend to aggregate due to their large surface to volume ratio exhibiting strong superparamagnetic properties. Physiochemical properties such as the particle size, distribution, and concentration are invaluable for adjusting the optical and magnetic properties. Combinatorial therapies assisted by iron oxide nanoparticles are indicated in cancer therapy. Fe_3O_4 nanoparticles can provide targeted drug delivery and enhance imaging and therapeutics through high localization at the target site under magnetic field. Synergistically these nanoparticles also cause tumor cell death via localized hyperthermia under alternating magnetic fields and/or photon application (with therapeutic agents) that generates heat (4).

Multiple techniques are applied for the synthesis of magnetic nanoparticles. Although coprecipitation of iron salts is the most common method, desired size range and nonuniform distribution of the particle are some of the drawbacks (5). Sonolysis, electrospray synthesis, flow injection synthesis, polyol method, sol-gel reaction, hydrothermal synthesis, and microemulsions are just a few of these techniques. Naked iron oxide nanoparticles are highly unstable. This material oxidizes in air due to strong chemical activity from the large surface to volume ratio that leads to loss of magnetism and dispersibility. To enhance the stability of the particles, the particles are often surface modified or coated to protect the nanoparticle as well as to introduce advanced functionality. Both organic and inorganic compounds can be conjugated for surface functionalization (5).

Magnetite powder was obtained in laboratory conditions by co-precipitation. Co-precipitation is the process of preparing wetted magnetite particles and consists in adding a basic solution to a solution containing iron ions (II) and iron ions (III) in stoichiometric proportions to achieve a certain pH value. Co-precipitation has the advantages over the conventional ceramic procedure by simple and rapid preparation of the compounds; reproducibility of the chemical composition; good control over the particles dimensions distribution by

parameters of co-precipitation process. Temperature is an important factor in co-precipitation process, determining the primary size of crystals, specific surface and even the phases that form.

The research focused on the development of some new nanoparticles suitable for use as contrast agents and assessment of the impact of the newly developed nanoparticles on gastric cell line AGS viability, in order to be used for terahertz imaging.

MATERIAL AND METHODS

A. Nanoparticles preparation

The experimental setup for magnetite synthesis. Magnetite obtainment: precise quantities of $FeCl_3x6H_2O$ and $FeCl_2x4H_2O$ were dissolved in degassed water (by nitrogen flux) and the resulting solution was transferred to a flask with 3 neck flasks in a preheated water bath at 75°C. Subsequent, to the cationic iron solutions was added a basic 25% solution of NH_4OH, with the role of co-precipitation agent. After a short time, a black precipitate corresponding to magnetite was observed. The mixture was maintained under stirring for 30 minutes, whole process being realized under controlled atmosphere by introduction of a constant nitrogen flow. The solid product (magnetite) was separated by magnetic decantation, washed with distilled water for the elimination of basic solution excess and dry in oven, at 50°C for 12 hours.

Functionalization of magnetite with citric acid. The dispersion and stabilization of magnetite (Fe_3O_4) in citric acid supposed the dispersion of iron oxide in distilled water and heating of the obtained magnetic fluid at 90°C with continuous mechanical stirring and ad of concentrated citric acid solution. The mixture thus prepared was kept continuous stirring for 1 hour, at 90°C.

Functionalization of magnetite with carboxymethylcellulose. The functionalization of the magnetite with carboxymethylcellulose was accomplished by using a magnetic fluid as that obtained previous for stabilization in citric acid. The magnetic fluid was sonicated for 15 minutes, after which a solution of carboxymethylcellulose was added. The resulting mixture was sonicated for 1 hour at 50°C.

Gadolinium oxide. Dispersion and stabilization of gadolinium oxide (Gd_2O_3) in citric acid was carried out as follows: the oxide powder was dispersed in water by sonication for 10 minutes, followed by add a solution of concentrated citric acid to the dispersion. The prepared mixture was sonicated for one hour at room temperature. The TEM micrograph demonstrates that dispersion and stabilization of Gd_2O_3 in tricarboxylic acid has led to a decrease in agglomeration degree.

Functionalization of gadolinium oxide with carboxymethylcellulose was performed with the same methodology as used for the dispersion of magnetite.

B. In vitro assay

Cell line. AGS (Human Gastric adenocarcinoma cell line, CLS 300408) cells were cultivated in a DMEM medium (Dulbeco's Modified Eagle's Medium, Biochrom AG, Germany), supplemented with 10% fetal bovine serum (FBS, Biochrom AG, Germany) and also with 100 µg/mL streptomycin (Biochrom AG, Germany), 100 IU/mL penicillin (Biochrom AG, Germany). The cell cultures were seeded in a 24 well plates (20,000 cells/well) and maintained in a CO_2 incubator, at 37°C.

C. Viability Assay. Cells were seeded in 24 well plates and were allowed to grow

overnight. After the medium was discarded and cells were washed, the renewal complete medium was supplemented with the tested nanoparticles (C = magnetite/Fe_3O_4 stabilized in diluted citric acid; D = magnetite/Fe_3O_4 stabilized in carboxymethylcellulose; E = Gd_2O_3 stabilized in carboxymethylcellulose) in consecutive dilutions of 0, 1:100, 1:75, 1:50, 1:25, 1:10, 1:5, 1:1. Duration of treatment was of 24 hours and the cell viability was assessed by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetra-zolium bromide) test. After treatment time has expired, the medium was discarded; cells were washed with PBS (phosphate-buffered saline) and covered with 100 µL fresh complete medium. 10 µL of MTT (5 mg/mL) were added in medium and cells were incubated for 3 hours. To solve the formed formazan DMSO (dimethyl sulfoxide, Merck) was used and the absorbances were recorded at 570 nm (1). Cellular viability (%) was calculated according to the formula: % cell viability = [Absorbance]sample / [Absorbance]control x100.

RESULTS AND DISCUSSION

Magnetite characterization

Magnetite was characterized by X-ray diffraction and transmission electron microscopy (TEM). X-ray powder diffractogram of the synthetized material is depicted in figure 1. The identification of the crystalline phases from diffractogram is based on the data of powder diffraction data from JCPDS (Joint Committee on Powder Diffraction Standards) database.

All the diffraction peaks from figure were identified and indexed according to JCPDS card no. 19-0629. Formation of magnetite with spinel structure is confirmed by the exclusive presence of maximum peaks for the plans (2 2 0), (3 1 1), (2 2 2), (4 0 0), (4 2 2), (5 1 1), (4 4 0), (6 2 0), (5 3 3). The presence of the narrowed peaks indicates a very high crystallinity grade for synthetized magnetite.

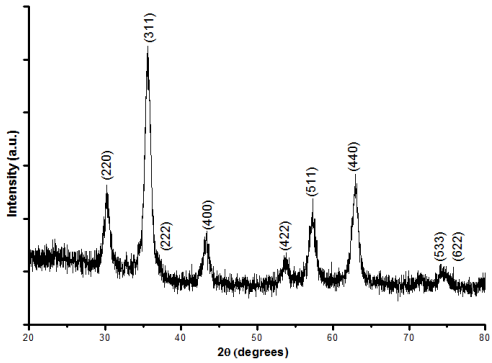

Fig. 1. X-ray diffractogram of magnetite / Fe_3O_4

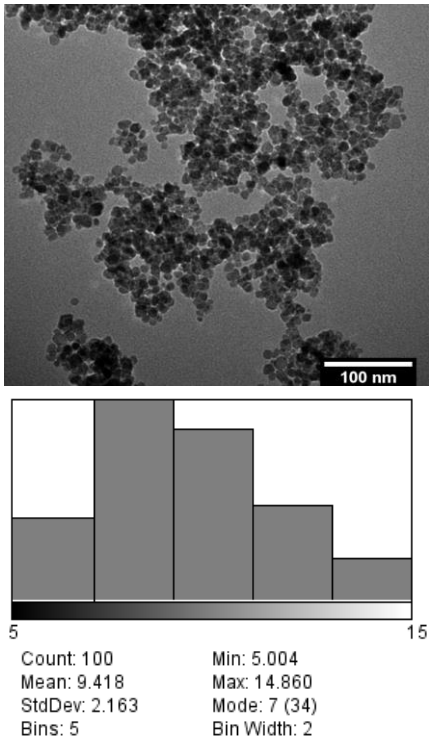

Fig. 2. TEM micrograph of magnetite/Fe_3O_4 and its size distribution

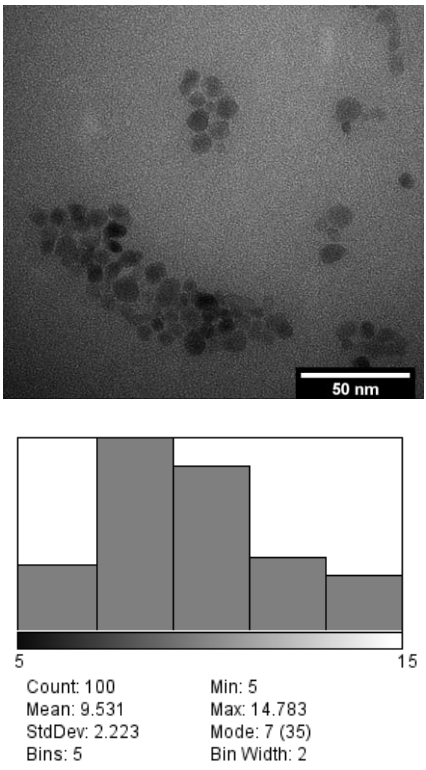

Fig. 3. TEM micrograph of magnetite/ Fe_3O_4 stabilized in citric acid and its size distribution

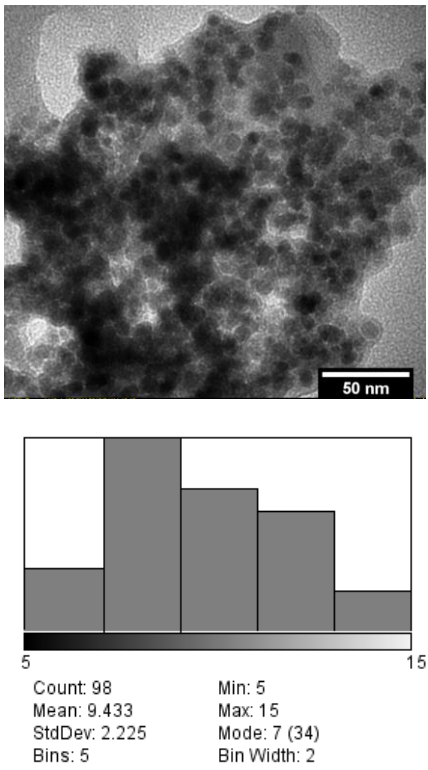

Fig. 4. TEM micrograph of magnetite/ Fe_3O_4 stabilized in carboxymethyl cellulose and its size distribution

Morphology of magnetite was studied by TEM microscopy (fig. 2), the mean size and size distribution of the particles were estimated with a dedicated software and taking in consideration minimum 100 repetitions. Analysis of TEM micrograph and particle size distribution showed that obtained magnetite nanoparticles have presented a regulated shape, almost spherical, with a degree of agglomeration relatively high. The mean size of the magnetite nanoparticles was of 9.418 nm, with sizes from 5 to 15 nm.

Characterization of magnetite functionalized with citric acid by TEM. The materials obtained were analyzed by electronic microscopy. TEM micrograph of stabilized magnetite in citric acid is shown in figure 3. There is a decrease in the agglomeration degree due to dispersion in the tricarboxylic acid. It is important to note that the stabilization process does not influence the mean particle size and the magnitude distribution of the magnetic nanoparticles.

Characterization of magnetite functionalized with carboxymethyl cellulose by TEM.

TEM analysis of the magnetite functionalized with carboxymethylcellulose (fig. 4) highlights the presence of the cellulose derivative in the vicinity of the inor-

ganic component of the system. Similar to the previous case, the functionalization with carboxymethylcellulose does not affect the magnitude particle size distribution or the average size.

Gadolinium oxide. The gadolinium oxide was characterized by electronic microscopy (fig. 5). It was observed that it is in the form of irregular and extremely agglomerated particles. After dispersion and stabilization, gadolinium oxide (Gd_2O_3), TEM analysis has demonstrated that dispersion and stabilization of Gd_2O_3 in tricarboxylic acid has led to a decrease in agglomeration degree.

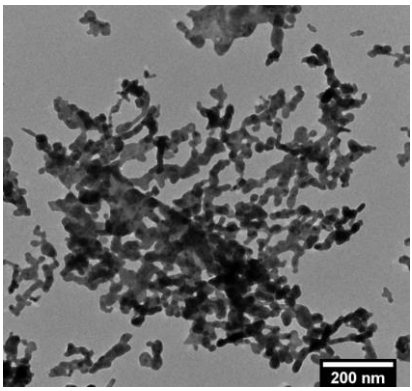

Fig. 5. TEM micrograph of Gd_2O_3

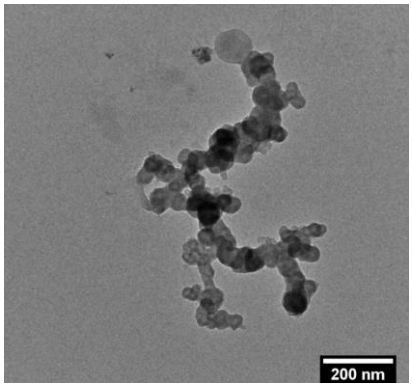

Fig. 6. TEM micrograph of Gd_2O_3 stabilized in citric acid

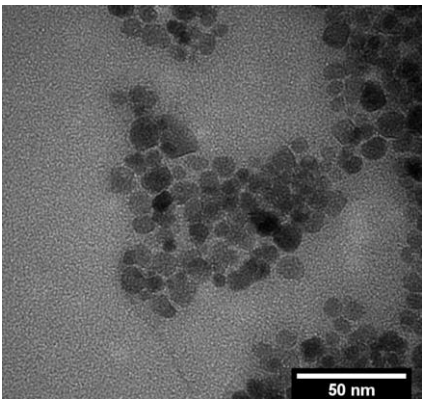

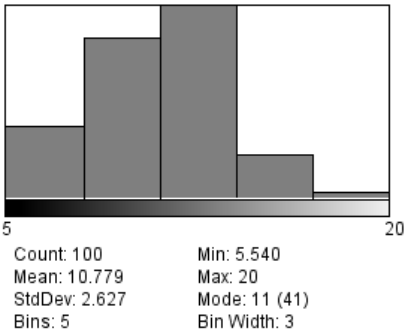

Fig. 7. TEM micrograph of Gd_2O_3 functionalized with carboxymethylcellulose

Characterization of gadolinium oxide functionalized with carboxymethylcellulose by TEM.

The functionalization of gadolinium oxide with carboxymethylcellulose was performed with the same methodology as used for the dispersion of magnetite. From the TEM analysis, we can see that the functionalization process allows deagglomeration of the inorganic particles in the presence of the considered polymer (fig. 6). Thus, the functionalized gadolinium oxide particles have dimensions ranging between 5 and 20 nm, with an average of 10.779 nm (fig. 7).

Cell viability was determined by MTT assay after 24 hours of incubation of AGS

cells in the presence of different dilutions of nanoparticles. The impact on cell survival was dependent by concentration of the nanoparticles added to the media.

TABLE I.
Cell viability of AGS cells as determined after 24 hours from add of nanoparticles C-E in dilutions of 0, 1:100, 1:75, 1:50, 1:25, 1:10, 1:5, 1:1.

Fe_3O_4 nanoparticles (C, functionalized in citric acid, and respectively D, functionalized in carboxymethylcellulose) has induced a smaller amount of cytotoxicity at the first two dilutions, followed by an increase of the cytotoxic effect with the maxim effect at the dilution of 1:1 (42% and respectively 54%). In this case, an important role in the induction of the cytotoxic effect seems to be due nanoparticles themselves, as the presence of different functionalizing agents didn't cause high variations of cells survival. Also, the dose-effect relationship Gd_2O_3 stabilized in carboxy-methylcellulose (E) presented a moderate cytotoxic impact in the range of 1:75 to 1:5 dilutions, followed by registration of a significant toxic effect at 1:1 dilution (50%).

Analysis of the results, as the result of viability quantification at the highest dilution used, shows that C-E nanoparticles functionalized either with citric acid or with carboxymethylcellulose are well tolerated by AGS cells. Also, in the range of 1:100 to 1:5, the impact on cell viability is reduced or moderate, confirming that these types of nanoparticles aren't cytotoxic for the cancerous gastric cells.

There are two factors which could influence the impact of nanoparticles on cell viability: the concentrations of nanoparticles: smaller dilutions will contain higher numbers of the nanoparticles which will be deposit on higher areas of cell culture plate, impairing cell adhesion and subsequently cell survival; concentration of the functionalizing agents (citric acid and carboxymethylcellulose) which could change the normal cell culture environment.

CONCLUSIONS

Tested nanoparticles (C-E) functionalized either with citric acid or with carboxymethylcellulose are well tolerated by AGS cells.

The other studied nanoparticles are well tolerated, but with the reduction of the dilution, the cytotoxic impact on cell cultures is higher.

NEWS

IMPROVED OVARIAN RESPONSE TO STIMULATION AND EMBRYOLOGICAL PARAMETERS IN YOUNG WOMEN WITH POOR OVARIAN RESERVE IN IVF-ICSI CYCLES AFTER TREATMENT WITH COQ10

One of the major challenges in reproductive medicine is to manage the women with reduced ovarian reserve or poor ovarian response (POR) to stimulation. The most important contributors of poor ovarian response are oxidative stress. In a study published in Reproductive Biology and Endocrinology, the authors evaluated the association on pretreatment with coenzyme Q10 and ovarian response and embryo quality in young low-prognosis patients with POR. The study group included 69 participants (76 treated with CoQ10 for 60 days preceding IVF-ICSI cycle and 93 controls). The results showed that women in CoQ10 group had increased number of retrieved oocytes, higher fertilization rate and more high-quality embryos. These results sustain the role of pretreatment with CoQ10 in improving ovarian response to stimulation and embryological parameters in young women with poor ovarian reserve in IVF-ICSI cycles.(Xu Y, Nisenblat V, Lu C, Li R, Qiao J, Zhen X, Wang S. Pretreatment with coenzyme Q10 improves ovarian response and embryo quality in low-prognosis young women with decreased ovarian reserve: a randomized controlled trial. *Reprod Biol Endocrinol*. 2018 Mar 27;16(1):29. doi: 10.1186/s12958-018-0343-0).

GINGIVO-PERIODONTAL MANIFESTATIONS IN CHILDREN WITH LEUKEMIA: A LITERATURE REVIEW

GINGIVO-PERIODONTAL MANIFESTATIONS IN CHILDREN WITH LEUKEMIA: A LITERATURE REVIEW (Abstract) **Objectives:** The purpose of this paper was to review the current literature concerning oral manifestations in children with leukemia. The main signs and symptoms recognized in these patients, emphasizing the gingivo-periodontal manifestations and symptoms, were investigated. **Background:** Leukemias represent about 30% of childhood cancers, acute lymphoblastic leukemia (ALL) being by far the most common form in children. The most frequent oral manifestations of leukemia are gingival bleeding, generalized hyperplasia, gingival erythema, petechiae. Often, these are the first hints for the disease, therefore, the dental practitioner is very much challenged in recognizing the main oral manifestations of this impairment, in order to make an early and efficient diagnosis. **Methods:** Medline database (via PubMed) was searched, using MeSH terms. Moreover, other physical sources, represented by articles and published papers relevant for the proposed theme were used. **Results:** Main oral signs and symptoms highlighted in children with leukemia were noted. The most frequent oral and gingivo-periodontal manifestations observed in this type of disease are gingival edema and erythema, spontaneous gingival bleeding, ulcerations, petechiae, opportunistic infections (Herpes, Candida, bacterial infections), dental mobility, generalized gingival hyperplasia. **Conclusions:** Dental practitioners should be aware of the main oral signs and gingiva-periodontal manifestations that can be present in children with leukemia. Very often, these are the first manifestation of the mentioned disorder, and the dentist is the first to remark them and refer a patient to a complex systemic evaluation and a proper diagnosis. **Keywords:** LEUKEMIA, CHILDREN, ORAL MANIFESTATIONS, PERIODONTAL MANIFESTATIONS.

Worldwide, in children and adolescents, cancer tends to exceed infectious diseases as a mortality cause. For children populations in Europe, North America and other developed regions of the world, incidence rate of cancer is about 140 in one million. In the United States, cancer is the second mortality cause in children, after accidents (1). According to the European Society for Pediatric Oncology (SIOPE), 15,000 new cases are diagnosed every year in Europe, and each year over 3,000 children and adolescents die of cancer, which still remains the leading annual cause of death by disease in Europe

(2). In Romania, an incidence of 7.35 in 100,000 children and a distribution of types of tumors similar with international statistics has been reported (3).

According to the literature data, almost 30% of children cancers are leukemias (4). Moreover, in Brazil, leukemia is the main cause of death by cancer in children (5).

The classification of leukemias is complex, and all the types can be found in detail in the World Health Organization's classification of hematopoietic and lymphoid tissues tumors, published in 2001 and revised in 2008 (6). Leukemias can be thus generally classified based on the primary cell line of origin in lymphoid or myeloid leukemia. Further, according to their evolution, leukemias can be divided into acute or chronic (7). hence, one can distinguish 4 main types of leukemia: acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), chronic lymphoid leukemia (CLL) (8).

Acute lymphoblastic leukemia is the most common form in children, consisting in about 75% of the newly diagnosed leukemias and 25% of all malignant diseases of the child (6). The etiology is still uncertain, but a few causal factors have been proposed: viral infections, exposure to ionizing radiation and chemicals (benzoic derivatives, heavy metals, pesticides) and also immunologic factors (9). Some studies indicate environmental factors like: smoking and alcohol consumption in parents, bacterial infections, chemical substances, exposure to electromagnetic radiation and electric fields, as well (10).

The purpose of this paper was to scrutinize the existing literature for the current data regarding the correlation between oral manifestations and leukemia in children, with strength upon the most common gingival and periodontal signs observed in children with leukemia.

MATERIAL AND METHODS

The articles used were accessed from Medline database (via PubMed), using the following MeSH terms: "oral manifestations" and "leukemia" and "children" and "gingival manifestations" and "periodontal manifestations". The literature search continued by hand, for printed articles and publications with the same criteria as with the electronic search.

RESULTS

Historically, the connection between specific oral signs and acute leukemia was first noted in 1964, by Roath (11) in a study which reported 20% of acute leukemia patients also presented with "buccal lesions" observed that 58% of acute leukemia patients studied presented with oral signs of the disease (12). In a study of Tagaki 50% of the 16 patients with acute leukemia studied were first seen by a dentist, for oral problems (13). Stafford reported that dentists were responsible for referring patients to hematological tests, which later led to diagnosing leukemia based on suspicions raised by oral manifestations in a quarter of the patients with acute myeloid leukemia and a third of patients with acute myelomonocytic leukemia (14). All these papers evaluated the correlation between leukemia and oral manifestations, disregarding age.

In present time, modern oncology requires the presence of the dentist in each treatment phase and even before the diagnosis, for the management, maintenance of oral health and life quality of patients with leukemia (15).

The oral cavity represents, to some extent, the interface between oral and systemic health, some oral diseases being able to affect general health, or reflect a manifestation of systemic homeostasis (16). For instance, multiple caries may lead to difficulties in the growth and development of the

child (directly by nutrition, or indirectly by chronic pain and its consequences). Vice versa, it is known that systemic diseases may alter oral health status by defectuous dento-facial development, altering the oral physiology and compromising patient's ability to maintain oral health (17).

Schlosser *et al.* (18) note that the mechanisms of oral pathology in hematological diseases like leukemia may be direct infiltration through abnormal hematological cells, formation and deposit of abnormal proteins, oral ulcerations and abnormal hematopoiesis.

According to Philipone (19), clinical manifestations of leukemia in general, result from loss of normal leukocyte function, suppression of hematopoietic cell lines, or by direct infiltration of leukemic cells in tissues. Thus, systemic signs and symptoms may include fatigue, anemia, lymphadenopathy, recurrent infections, bone and abdominal pain, bleeding and petechiae. Oral manifestations involve the mucosa and may be gingival bleeding, petechiae, ulcerations. Patients are also susceptible to severe viral, bacterial or fungal infections, as a consequence of immunosuppression. Gingival leukemic infiltrate leads to edematous, erythematous and friable gingiva.

McCord *et al.* (8) describe the following main oral signs and symptoms in children with leukemia: neutropenic ulcerations, spontaneous gingival bleeding, opportunistic infections (like: *Candida albicans*), and in chronic lymphoid leukemia – the possibility of developing paraneoplastic pemphigus.

Hou *et al.* (20) have shown that oral manifestations may appear in any type of leukemia but are more prevalent in acute leukemias (as in chronic leukemias) and myeloid leukemias (as in lymphoid leukemias). In his study, McKenna (21) suggests that deep, painful oral ulcerations are common in leukemic patients. Eisen *et al.* (22) stated that oral examination of patients with leukemia may reveal mucosal pallor due to anemia, or bleeding and petechiae in the palate, lingual or labial regions, as a result of thrombocytopenia.

In a recent study, Casamassimo describes several oral manifestations in lymphoid leukemia, as following: mucogingival pallor, purpura, spontaneous gingival bleeding, necrotic ulcerations, herpes infections, candidiasis, bacterial infections, dental mobility, aggressive periodontitis, periapical radiolucency, paresthesia, facial edema, lymphadenopathies in head-neck region. For the myeloid leukemia, the author reports diffuse gingival enlargements and masses of soft edematous tissue in the oropharyngeal region (16).

In children and adolescents, clinical aspects and manifestations of periodontal diseases are different than those seen in adults, one of the major differences being gingivitis (it is more frequently seen in children, whereas periodontitis develops more rarely). Such differences disappear in children with associated systemic diseases, particularly leukemia.

In 2012, Pels *et al.* have studied 156 children (78 with acute lymphoid leukemia and 78 with unaltered systemic homeostasis) from rural and urban regions in Poland (23). They have analyzed oral hygiene status and the results suggested a precarious oral hygiene in children with leukemia from rural regions, compared to leukemic children in urban regions. The oral hygiene was better in children with acute lymphoid leukemia compared to healthy subjects, because of their rigorous oral hygiene regime. However, the gingival indices evaluated (simplified oral hygiene index – OHI, plaque index – PI and gingival index – GI) were more elevated in leukemic children, indicating a higher risk of mucositis, despite a more important preoccupation for maintaining oral hygiene. In a previous study from 2007, the same

authors have reported similar results – they noticed a better oral hygiene and a lower incidence of plaque in children with acute lymphoid leukemia (24).

In 2011, Hedge *et al.* (25) have evaluated periodontal health status in 120 children with and without acute lymphoid leukemia. The authors have noticed the presence of gingival inflammation more often in children with ALL than in healthy subjects. Ponce-Torres *et al.* (26) have conducted a study in 2010 on 49 children with ALL, reporting a prevalence of 91,84% for gingivitis and 16,32% for periodontitis in these children. Literature data are somewhat inconsistent, especially considering the geographical distribution of populations, some reports from the beginning of this millennium indicating a much lower incidence, about 10-17% for these gingival manifestations in children with leukemia (27, 28).

Morais *et al.* (29) have reported, as the most common oral manifestations in children with leukemia, the following: gingival bleeding, hyperplasia, opportunistic infections and bone alterations. Previously, the most common oral manifestations observed were gingival edema caused by leukemic infiltrate, gingival hyperplasia usually being generalized and different in severity (30).

Baliga *et al.* have studied, in 1995, patients with acute lymphoid leukemia, and the most suggestive signs of leukemia they revealed were: lymphadenopathy in the head-neck region, along with gingival bleeding and mucosal pallor (31). In another study of 77 patients with ALL, poor oral hygiene, infections due to medullary and immune system suppression and altered healing responses were reported (28).

In a recent study on 3,789 children under 12 years of age, the authors reported that oral manifestations were a big contributor to the diagnosis of leukemia for 6% of the patients (32). The most common oral signs observed were gingival bleeding, petechiae, ecchymosis, mucosal alterations and fungal lesions. In another study, gingival bleeding was observed as a first symptom of leukemia in children for 17% of acute cases and 4% of chronic forms (33).

The importance of a complex systemic evaluation in the context of suggestive oral signs is also underlined by Safari *et al.* (34) in a case study in 2016. Along other unspecific general symptoms such as bone pain, a 9-year-old patient presented to the dentist for dental pain, dental mobility, erythema and gingival edema. He was later referred to the pediatric and hematology department, where the suspicion for lymphoid acute leukemia was confirmed.

In 2002, Katz and Peretz have reported a case of acute lymphoid leukemia diagnosis based on the presence of dental trismus (35). The trismus was probably caused by the infiltration of leukemic cells in the deep portions of facial muscles. With their study, the authors underlined the importance of clinical and laboratory exams recommended by the dentist.

In a case study in 2014, Kolli *et al.* (36) have identified distinctive signs of acute necrotizing ulcerative gingivitis (AUNG-GUNA) associated to acute lymphoid leukemia: patient presented the classic triad of pain-bleeding-ulceration, along with secondary signs like sub febrile state and decapitated gingival papilla, covered with pseudo-membranes.

In present, there are tendencies in the literature to systematize, in a standardized fashion, the most common oral manifestations in general, and gingival-periodontal manifestations in particular, ascertained in children with leukemia. The dentist should know and differentiate these signs and symptoms during the protocols for clinical examination. This would allow a higher success rate of an interdisciplinary early

diagnosis issued by the cooperation between the dentist and pediatrician/hematologist, for children with leukemia. To accomplish these needs of standardization and systematization, further studies are required.

CONCLUSIONS

Considering the growing prevalence of these diseases, children leukemia must be approached in a complex generalized systemic manner, in which the dental practitioner has a significant contribution. He often is the first one to observe signs and specific symptoms of the disease in the dental office. Among these oral signs, the gingiva-periodontal manifestations are the most common, hence every dental practitioner should be aware of, and able to relate their presence in the oral cavity with the possibility of leukemia.

CLOSTRIDIUM DIFFICILE INFECTION IN PATIENTS WITH TYPE 2 DIABETES MELLITUS. THE EXPERIENCE OF AN INFECTIOUS DISEASES HOSPITAL FROM NORTH-EASTERN ROMANIA (Abstract): *Clostridium difficile* infection (CDI) in patients with other comorbidities such as diabetes mellitus (DM can set special diagnosis and management problems. **Material and methods:** Retrospective study comparing two groups of consecutive patients (group 1: 71 cases with DM, group 2: 336 cases without DM) diagnosed with CDI in the Iasi Infectious Diseases Hospital from January 1, 2016 to January 1, 2017. **Results:** Mean age, the proportion of patients over 60 years, as well as the proportion of cases with community-acquired infections were significantly higher in group 1. Clinical manifestations were similar in both groups, except for the greater amplitude of fever in group 2. Group 1 patients had a slightly higher frequency of the severe forms of CDI and higher serum creatinine levels compared with group 2 patients. The rate of recurrent CDI did not significantly differ between the two groups, but the age of relapsing diabetic patients was higher. Lethality was not influenced by the presence of diabetes. **Conclusions:** Patients with CDI and type 2 DM were older, had more community-acquired infections, some clinical features of the disease compared to nondiabetic patients. **Keywords:** DIARRHEA, FEVER, ANTIBIOTICS, RELAPSE.

Clostridium difficile infection (CDI) is an important issue for both healthcare providers - being recognized today as the most common cause of health care-associated diarrhea (1) - as well as for the patients in the community. *Clostridium difficile* (CD) is widely found in the environment. Human contamination probably occurs by ingestion and can lead to long-term colonization or symptomatic infection due to competition with normal gut flora (2).

Other than a greater amplitude of fever and other undesirable effects (related to resistance, toxicity, etc.), uncontrolled and inappropriate administration of broad-spectrum antibiotics, also causes each time a disruption of the equilibrium of nonpathogenic intestinal flora, which fosters the development of highly pathogenic CD strains (3).

Due to the secondary impairment of the immune system (4), patients with diabetes

are at higher risk for developing infection (urinary, respiratory, skin, bone, sepsis or peritonitis) (5) and thus receive antibiotics more frequently. Numerous studies (6, 7, 8) have shown that the risk of CDI is increased in diabetic patients, in which recurrent infections are more common. In these patients, the use of metronidazole was linked to an increased risk of CDI treatment failure (9). Some authors (10) suggest that metformin treatment seems to have a protective effect against CDI development.

In this study, we aimed to highlight differences between diabetic and nondiabetic patients with CDI in order to optimize the early management of this category of patients.

MATERIAL AND METHODS

This retrospective comparative study included consecutive patients diagnosed with CDI at the Iasi "Sf. Parascheva" Clinical Hospital for Infectious Diseases between January 1, 2016 and January 1, 2017. Diagnosis of CDI was based on the immunochromatographic detection of toxin A only and/or toxins A and B in stool of patients presenting more than 3 loose stools per day. Recurrence of infection was defined as reappearance of diarrheic syndrome with positive test for CD toxins within 3 months of the previous episode.

The patients were divided into 2 groups according to the presence/absence of diabetes mellitus (DM): group 1 - patients with CDI and type 2 DM and group 2 - patients with CDI without DM. The following data were collected: demographics, history of antibiotic use, as well as clinical data related to short- and medium-term recurrences (re-admission within up to 3 months after discharge), laboratory data and etiological treatment.

Statistical analysis. The *Chi-squared* and *t-Student* tests were used for statistical analysis and a p value < 0.05 was considered as statistically significant. The objectives and procedures of this study were approved by the Ethics Committee of the Iasi Hospital for Infectious Diseases. No written consent was given by the participants, as data were collected and analyzed anonymously.

RESULTS

During the analyzed interval a number of 407 patients with CDI were included in the study, of which 71 (17.4%) with DM.

TABLE I

Characteristics of patients with CDI

	Group 1 (+ DM) n=71		Group 2 (- DM) n=336		*p*
	N	%	N	%	
History of previous antibiotic use	62	87.3	286	85.1	0.76
Surgical interventions	14	19.7	60	17.8	0.87
Healthcare facility-onset (HO) CDI;	38	53.5	204	60.7	**0.008**
Community-onset, healthcare facility-associated (CO-HCFA) CDI	20	28.2	109	32.4	
Community-associated (CA) CDI	13	18.3	23	6.8	
Mean age (years)	63±4		58±3		**0.03**
Sex (M/F)	34/37		180/156		0.49
Rural/urban area of residence	31/40		164/172		0.51

Mean age of patients in group 1 was higher than in group 2 (p = 0.03), and more group 1 patients were over 60 years, compared to group 2 (64.8% *vs.* 51.8%, p = 0.04) (tab. I).

The average duration of diarrheal syndrome was of 7.6±1.1 days in group 1, compared to 8.38±1.3 days in group 2 (p = 0.67). Amplitude of fever was higher in group 2-30 (8.9%) patients presented with >39°C, as compared to 2 (2.3%) patients in group 1 (p=0.067) (tab. II).

TABLE II

Clinical manifestations

	With DM		Without DM		p
	N	%	N	%	
Fever	11	15.49	63	18.75	0.52
Abdominal pain	52	73.24	245	72.92	0.98
Vomiting	15	21.13	75	22.32	0.82
Watery stools	40	56.33	211	62.79	0.31

TABLE III

Toxins identified in patients' stool

Group	A		B		A and B	
	N	%	N	%	N	%
With DM (71 - 17.44%)	6	8.45	23	32.39	42	59.16
Without DM (336 - 82.56%)	40	11.9	135	40.18	161	47.93
p	0.403		0.221		0.047	

Diagnosis of CDI was confirmed following the identification of toxins in patients' stool by means of immunoenzymatically assay. In group 1, both toxins were more commonly present (59.16%) as compared to group 2 - 47.93% (p = 0.047) (tab. III).

TABLE IV

Analyzed laboratory variables

	Group 1		Group 2		p
	N	%	N	%	
Urea (BUN) >40 mg/dL	39	54.9	139	38.4	0.02
Creatinine > 1.5 mg/dL	24	33.8	78	23.21	0.04
Leucocytes > 15,000 / mm^3	16	22.5	52	15.5	0.20
ALT > 35 UI/L	26		15		0.49

Severe forms of CDI (according to SHEA/IDSA 2010 criteria) were identified in 26 (36.6%) patients in group 1 as compared to 98 (28.5%) patients in group 2 (p=0.1) (tab. IV).

The same therapeutic approach was

used in both study groups; anti-CD acting antibiotics available on the Romanian market were used, the most commonly used being metronidazole (60.5% of the cases *vs.* 63.1%) (tab. V).

Ninety-six (23.6%) patients presented recurrent CDI - 19.8% in group 1 *vs.* 22.9% in group 2 ($\chi^2 = 0.29$, $p = 0.58$).

TABLE V
Antibiotics used for the treatment of CDI

Antibiotics	Group 1		Group 2		*p*
	N	%	N	%	
Metronidazole	43	60.56	212	63.1	0.68862
Metronidazole + Vancomycin	12	16.9	54	16.07	0.86313
Vancomycin	12	16.9	58	17.26	0.94169
Other	4	5.64	12	3.57	0.41651

TABLE VI
Comparison between patient characteristics in recurrent CDI

	Group 1		Group 2		*p*
	N	%	N	%	
Fever	3	15.79	13	16.88	0.9
Vomiting	3	15.79	13	16.88	0.9
Abdominal pain	16	84.21	61	79.22	0.62
Latency period	5.9 ± 0.8 days		7.35±1.0 days		0.045
Sex ratio (F/M)	11/8		43/34		0.87
Mean age	70 ± 6 years		56 ± 5 years		0.006

Mean age of patients with diabetes who presented recurrence of CDI was significantly higher compared with that of patients without diabetes ($p = 0.006$) and the duration of symptoms was significantly shorter in diabetic patients (group 1, 5.9 *vs.* 7.3 days) (tab. VI).

In patients with recurrent CDI both toxins have been identified in a similar percentage of patients (50.9% *vs.* 49.8%) compared with the patients with initial CDI episode, but these were more commonly found among diabetic patients (73.7% *vs.* 59.2%) (tab. VII).

Lethality was not influenced by the presence/absence of DM (12.7% *vs.* 13.9%, $p = 0.15$) (tab. VIII).

TABLE VII
Toxins identified in patients with recurrent CDI

	A		B		A and B	
	N	%	N	%	N	%
+ DZ (19 - 19.79%)	1	5.26	4	21.05	14	73.69
- DZ (77 - 80.21%)	7	9.09	29	37.66	41	53.25
p	0.58874		0.17219		0.10676	

TABLE VIII

Patient lethality rate in the Infectious Disease Hospital during the studied period

	No patients	No deaths	Lethality rate (%)	p
All hospitalized patients	25598	471	1.8	-
CDI without diabetes	336	47	13.9	$p = 0.91$
CDI with diabetes	71	9	12.7	

DISCUSSION

In our study, the mean age of patients with CDI and diabetes was significantly higher compared to patients without type 2 DM (63 *vs.* 58 years, $p = 0.03$). Contrary to the results published by Lessa *et al.* (11), sex ratio was almost uniform in our patients and did not significantly differ between the two groups.

Exposure to antibiotics, age over 65 years, surgical interventions on the digestive tract, prolonged hospitalization, female sex, presence of diabetes mellitus, administration of proton pump inhibitors are risk factors for CDI quoted by various publications (12, 13). In our study, the average age of patients with CDI and diabetes was significantly higher compared to patients from group 2 (63 *vs.* 58 years, $p = 0.03$). Also, the proportion of patients aged over 60 years of age was higher among diabetic patients (64.8 *vs.* 51.8, $p = 0.04$). We can speculate that this category of patients, with a more frequent medical monitoring, is less prone the antibiotic misuse and overuse and acquire CDI later in life.

The vast majority of patients (87.3 *vs.* 85.1%) in both groups had received antibiotics before the diagnosis of CDI. According to recent studies (11, 12, 13, 14, 15) assessing the origin of CDI, up to 94% of cases are associated with health care (37% with Healthcare facility-onset). In our study, 59.5% of patients had Healthcare facility-onset CDI, 31.7% Community-onset, healthcare facility-associated CDI, and the remaining 8.8% had community-acquired infection. In the group of patients with diabetes, a significantly higher proportion of patients with Community-onset CDI (18.3% *vs.* 6.8%, $p = 0.008$) was identified. This fact could be explained by the more frequent use of antibiotics by persons with diabetes in an outpatient setting, although they may have more frequent contact with the medical system.

There were no significant differences in clinical manifestations between diabetic and nondiabetic CDI patients. Also, the percentage of patients with high fever was higher among the nondiabetic patients (8.9% *vs.* 2.3%, $p = 0.07$) probably due to the lower production of interleukins in response to infection; reduced chemotaxis and phagocytic activity in patients with diabetes (**Error! Reference source not found.**).

There are several criteria in use in assessing the severity of infection with CD (17) without any consensus with regard to the best. According to SHEA/IDSA 2010 criteria, in the group with diabetic patients a greater proportion of severe cases was identified (36.6 *vs.* 28.5%), but the difference is not statistically significant ($p = 0.10$). Among the severity factors most commonly identified in the diabetic patients, we should mention the proportion of patients with a creatinine over 1.5 mg% ($p = 0.02$), but this could this be the sign of a

pre-existing kidney disease.

The main pathogenic mechanism of CDI is the secretion of toxins during the vegetative phase of the germ, most notably toxins A (TcdA) and B (TcdB), that lead to local neutrophil infiltration and systemic inflammatory response (3, 18, 19). We noted a significantly more frequent detection of both toxins in patients with DM, compared with those without DM: 59.2% *vs.* 47.9%, $p = 0.04$.

Patients were treated according to the recommendations and guidelines with metronidazole or vancomycin, alone or in combination. A small percentage of patients received fidaxomicin (3 patients), rifaximin or symptomatic treatment alone. Some studies warn of an increased risk for metronidazole treatment failure in diabetics (9), but in the present study a relatively equal proportion of patients received this medication.

Regardless of the received therapy, patients in both groups had similar relapse rates- 19.8% *vs.* 22.9%, $p = 0.58$. Among patients with relapses, the mean age of diabetic CDI patients was significantly higher (70.1 *vs.* 56.4 years), and the length of the latency period of the development of CDI was shorter in the_nondiabetic CDI patients (5.9 *vs.* 7.3 days) probably due to the immune system particularities of diabetic patients (16).

Mortality rates for CDI were similar among diabetic and nondiabetic patients: 13.9% *vs.* 17.7% and 7.7 times higher than the overall mortality rates recorded in our hospital. For CDI, the figures are similar to those reported by Huart *et al*. and Iordan (20, 21).

The observational, retrospective nature of the study, not allowing any cause-effect conclusions, its one-center extension are the main limitations of the research. We also were unable to monitor all recurrences in patients admitted to our clinic with an initial CDI episode, some of them subsequently presenting to a family doctor who treated them in outpatient conditions or to a Diabetes and Metabolic Diseases Department (if the patient experienced an episode of decompensated diabetes), and thus contributing to a possible underestimation of CDI recurrence rate, especially in group 1 patients.

CONCLUSIONS

In our study, DM cases accounted for a significant proportion of the CDI patients treated in our hospital. Patients with CDI and type 2 DM were older, presented more community-acquired infections, and some clinical features related to lower frequency of fever and shorter latency period of the disease. No significant differences were found in terms of severity, relapse rate or failure of the various classes of antibiotics.

HEPATITA CRONICĂ VIRALĂ B – O PROBLEMĂ ÎNCĂ ÎN ACTUALITATE LA COPIL

Luiza Pohaci-Antonesei, Livia Bratu, Tania Rusu, Evelina Moraru
Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
Clinica a II-a Pediatrie
Spitalul Clinic de Urgenţe pentru Copii "Sf. Maria" Iaşi

CHRONIC HEPATITIS B – STILL A PROBLEM IN CHILDREN (Abstract): Vaccination of the newborns and adolescents had impact on the incidence of acute and chronic infection with hepatitis B virus (HBV) in children. After a decade of this national program application, authors proposed to study the epidemiologic dynamics of chronic infection with HBV in this interval, compared with the previous period, prior to vaccination. **Key words**: HEPATITIS B, VACCINATION, CHILDREN

Incidenţa infecţiei cronice cu VHB a rămas încă medie în ţara noastră, deşi din octombrie 1995 se practică vaccinarea nou-născuţilor în primele zile după naştere.

Prevalenţa AgHBs este, după datele epidemiologice recente, de aproximativ 6%. Supravegherea epidemiologică a infecţiei cronice cu VHB în România implică depistarea unor tendinţe epidemice, identificarea contacţilor care au nevoie de profilaxie post-expunere, definirea modalităţilor de transmisie, tratamentul formelor cronice active.

Riscurile de apariţie a copilului infectat sunt însă departe de a fi rezolvate, în condiţiile în care vaccinarea la naştere nu este completată cu măsuri specifice speciale, imunoprofilaxia pasiv-activă.

Progrese semnificative au marcat atitudinea practică a medicilor în abordarea infecţiei cronice cu virus hepatitic B la adulţi şi copii (1,2). Schemele terapeutice aplicate în ultima decadă pentru eficientizarea răspunsului terapeutic antiviral au avut însă rezultate care pot fi etichetate ca dezamăgitoare (maxim 30 % răspuns virusologic susţinut).

La aproape 35 de ani de când dr. Baruch S. Blumberg a fost recompensat cu Premiul Nobel pentru Fiziologie şi Medicină, datorită descoperirilor ***„concerning new mechanisms for the origin and dissemination of infectious diseases"*** şi pentru descrierea AgHBs, vaccinarea nu a rezolvat în totalitate problemele, deşi a avut efecte benefice considerabile în multe zone ale lumii. Primele descrieri ale mecanismului de replicare al VHB au fost publicate de William Robinson în 1970, când în virioni extracelulari s-a descoperit ADN-polimerază. În 1982, Jesse Summer şi Bill Mason au descris ADN-ul circular dublu catenar, revers-transcriptaza. Anul 1986 a însemnat anul introducerii primului vaccin obţinut prin inginerie genetică – vaccin recombinant VHB (3,4,5).

În epoca actuală de aplicare clinică a noilor analogi nucleozidici la adult, există studii limitate de utilizare a acestora şi la copii. Pe plan mondial cercetătorii se concentrează asupra unui aspect esenţial şi insuficient exploatat: utilizarea resurselor imune ale gazdei.

Focalizarea cercetărilor pe terapia imunologică implică şi cunoaşterea perfectă a

nuanţelor răspunsului imunologic al gazdei, pentru a identifica etapele ţintă pentru controlul total asupra infecţiei cu VHB (eradicarea infecţiei) (6,7).

Sistemul imun al copilului are multe particularităţi şi în aceste condiţii infecţia trece prin etape în care toleranţa imună caracteristică în primii ani după infecţie, poate trece în faza de interacţiune organism-gazdă, moment în care leziunile hepatice devin active. Imunosupresia, autoimunitatea, comorbidităţile infecţioase, toxice sau metabolice pot surprinde organismul vulnerabil al copilului (8,9).

Sunt elucidate astăzi modalităţile evolutive (particulare şi variate) în istoria naturală sau în cursul intervenţiilor terapeutice, în anumite etape ale vieţii, în relaţie strânsă în special cu vârsta la care s-a contractat infecţia cu VHB. Hepatologii au o viziune globală asupra diferenţelor evolutive ale infecţiei cronice cu VHB în relaţie cu vârsta la infestare.

În pediatrie, aspectele clinico-evolutive ale hepatitei B se prezintă astăzi sub noi paradigme, în relaţie cu aplicarea terapiei antivirale sau atitudinii profilactice globale (10). În România, eforturile multidisciplinare pot fi evocate ca succese, controverse dar si deficienţe.

Am efectuat un studiu retrospectiv si prospectiv, în Clinica a II-a Pediatrie UMF Iaşi, în perioada 1995-2009, prin care am studiat dinamica epidemiologiei hepatitei cronice virale B şi alte obiective.

OBIECTIVE

Obiectivele studiului au fost :

- prelucrarea parametrilor demografici reprezentativi pentru a caracteriza particularităţile de contactare a infecţiei virale hepatitice B, factorii de risc, populaţia susceptibilă, corelaţii între parametrii edificatori pentru aprecierea dinamicii fenomenului ;
- aprecierea modalităţilor de debut şi circumstanţelor clinico-biologice evolutive utile în elaborarea diagnosticului pozitiv
- perfectarea unui arbore decizional logic în formularea diagnosticului diferenţial şi precizarea comorbidităţilor ;
- aprecieri asupra terapiei, evoluţiei, toleranţei şi rezultatelor terapeutice la intervale variabile ;
- elaborarea unor concluzii generale practice.

MATERIAL ŞI METODĂ

Lotul de studiu a cuprins 159 de copii internaţi în Clinica II Pediatrie a Spitalului Clinic de copii „Sf.Maria" Iaşi în perioada 2004-2009, diagnosticaţi cu hepatită cronică cu VHB.

Criterii de selecţie şi includere în lot :

- Criterii generale : argumente clinice si biologice de diagnostic pozitiv pentru hepatita cronică cu VHB , Ag HBs pozitiv peste şase luni interval.
- Criterii speciale : AgHBe-/AgHBe+, seroconversia HBe sau apariţia tulpinilor mutante, viremia ADN-VHB , puncţia biopsie hepatică (PBH) sau Fibroscan.
- Observarea minim 6 luni şi supravegherea prin internări periodice în clinică.
- Complianţa familiei.

Urmărirea bolnavilor s-a realizat prin studiul retrospectiv al foilor de observaţie clinică şi întocmirea unei fişe cu principalii parametri urmăriţi în dinamica specifică fiecărui diagnostic şi tratament individualizat.

Criterii de diagnostic

Diagnosticul pozitiv a fost stabilit mai puţin pe criterii anamnestico-biologice şi în special pe criterii biologice şi serologice.

Elemente de reper din anamneză :

- motivele internării (astenia, durerile abdominale, anorexia, hepatomegalia, icterul sclero-tegumentar, infecţiile respiratorii recidivante, investigarea sindromului de citoliză descoperit în ambulator, copii proveniţi din mame infectate VHB) ;
- vârsta, sexul, mediul de proveniență al bolnavilor (instituţionalizarea, polispitalizarea) ;

• antecedente personale patologice reprezentate de transfuzii de sânge în antecedente (în special înainte de 1990), tratamente injectabile repetate, intervenţii chirurgicale, tratamente stomatologice, statusul nutriţional, co-infecţii virale, deficite imune, boli metabolice ;

• antecedente heredo-familiale motivate de posibilitatea transmiterii infecţiei cu VHB de la mama infectată sau infecţia intrafamilială (orizontală) (11,12) ;

• hepatita virală acută în antecedente.

Criteriul clinic – s-a apreciat starea generală, febra, astenia, hepatosplenomegalia şi eventualele semne extrahepatice.

Criteriile biologice au fost reprezentate de studiul sindroamelor fiziopatologice hepatice care au permis stabilirea diagnosticului pozitiv şi urmărirea în dinamică a evoluţiei, complicaţiilor şi ameliorării sub terapie.

Probele biologice s-au efectuat la diagnostic, după instituirea tratamentului şi apoi în dinamică, săptămânal în primele 4 săptămâni, apoi lunar. S-au determinat parametrii hematologici (hemoleucotrombograma), enzimele hepatocitare (ALT, AST, LDH) de apreciere a citolizei, gammaglutamiltranspeptidaza, fierul seric, enzimele pancreatice, parametrii sindromului hepatopriv (serinele, colinesterazele, timpul Quick, fibrinogenul), răspunsul imunologic (gamaglobulinele, markerii de autoimunitate) si valoarea bilirubinei, colesterolului, lipidelor şi lipidograma.

Criteriile serologice s-au apreciat prin teste calitative enzimatice ELISA sau RIBA (determinarea AgHBs, Ac anti HBs, AgHBe, Ac anti HBe, Ac anti HBc de tip IgM, şi IgG, Ac anti VHD) (3).

Prin protocoalele individuale s-au urmărit în etape markerii serologici la iniţierea tratamentului, la 3 luni de la începerea tratamentului, la finalul tratamentului şi la 6 luni de la terminarea acestuia.

REZULTATE ŞI DISCUŢII

În perioada 1995-2003 au fost internaţi cu hepatită virală cu VHB şi co-infecţii, 443 copii. În perioada 2004-2009 au fost internate 158 cazuri, ceea ce arată în mod cert beneficiile vaccinării.

În perioada 1979-1994 au fost diagnosticaţi 108 pacienţi, iar în perioada 1995--2003 au fost 356 de cazuri noi. Din prezentul lot de studiu, 69 de copii au fost diagnosticaţi înainte de anul 2004, în peri-

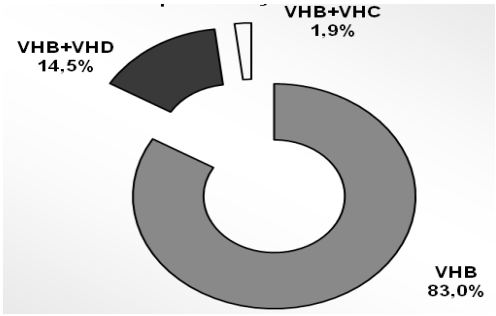

Fig. 1. Etiologia infecţiilor cronice hepatitice

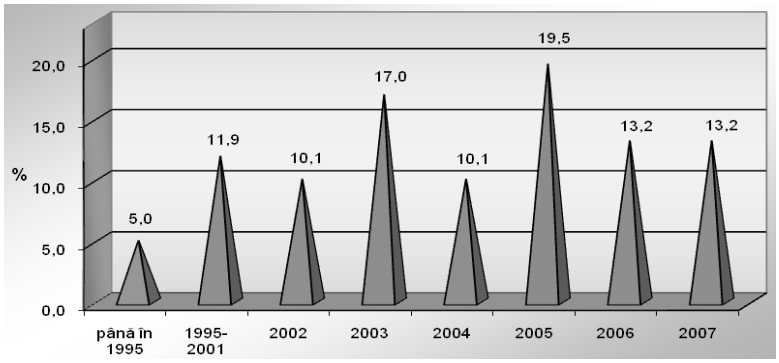

Fig. 2. Repartiţia pacienţilor în funcţie anul primei infecţii

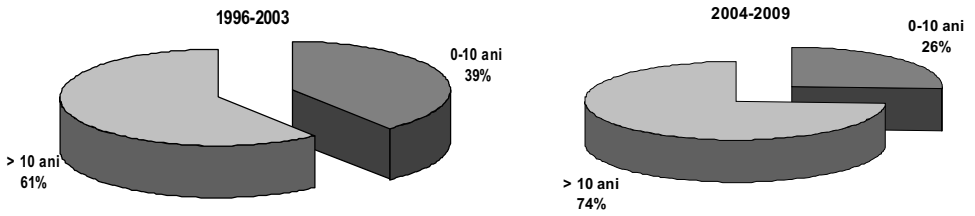

Fig. 3. Infecţia virală B - pe grupe de vârstă

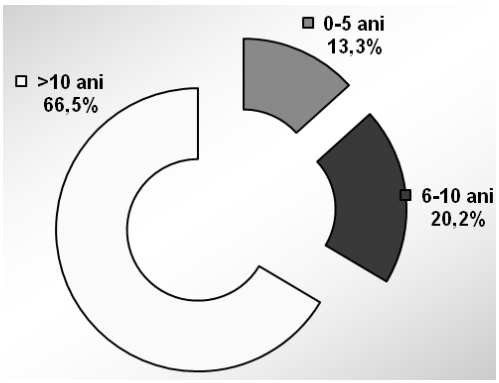

Fig. 4. Repartiţia cazurilor în funcţie de vârsta la diagnosticare

oada 2004-2009 fiind diagnosticaţi 89 de copii. După anul 2005 se remarcă tendinţa de scădere a fenomenului (hepatita cronică B).

Dacă înainte de 2004 predominau pacienţii diagnosticaţi la vârste sub 10 ani, în perioada 2004-2007 cei mai mulţi pacienţi aparţin grupei de vârsta de peste 10 ani.

În legătură cu dinamica grupelor de vârstă se poate remarca o menţinere a infecţiei la vârstă mică prin riscul infecţiei transmise de la mamele viremice.

În funcţie de vârsta la diagnostic se mai poate remarca vulnerabilitatea grupei 0-5 ani, perioada în care, se ştie, există riscul cel mai mare (până la 90%) de cronicizare a contactării infecţiei.

În intervalul de timp 1996-2009, după începerea vaccinării tuturor nou-născuţilor, riscul pentru infecţie la vârstă mică se menţine aparent surprinzător. La cazurile studiate vaccinarea a fost corectă logistic.

Calea de infectare a fost în special de la mamele cu infecţie cronică B ; multe dintre ele nu se ştiau purtătoare de virus.

Din totalul copiilor infectaţi în aceste perioade cazurile prin transmitere verticală reprezintă aproximativ 20%.

În funcţie de dinamica natalităţii se poate estima riscul acestei transmisii, tendinţă care va putea fi stopată doar printr-o profilaxie completă, care implică vaccinarea corectă, administrarea de imunoglobulină specifică şi asta din prima zi de viaţă.

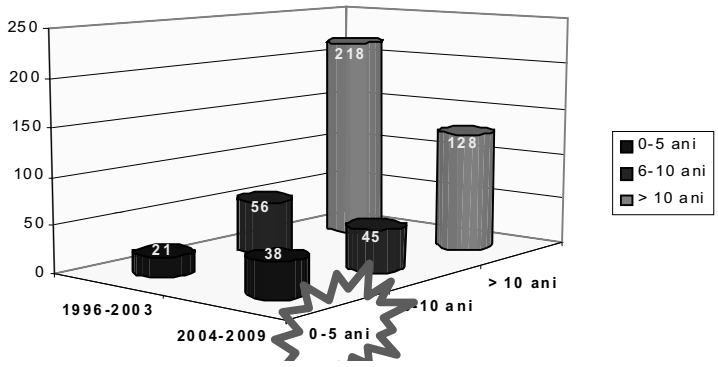

Fig. 5. Studiu cazuistic.

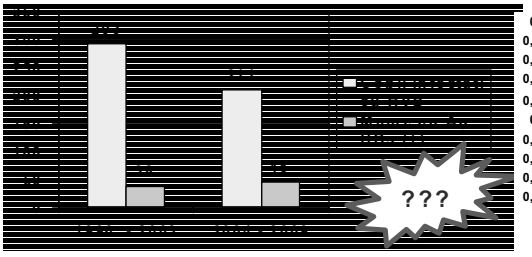

Fig. 6. Cazuri de infecţie cu HVB prin transmitere verticală

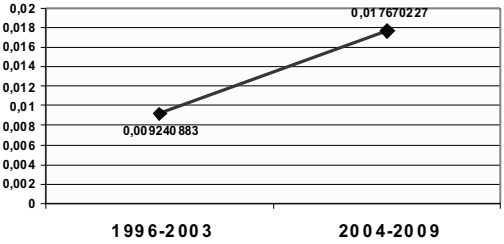

Fig. 7. Creşterea ratei transmiterii verticale a hepatitei cronice cu VHB

CONCLUZII

1. Vaccinarea împotriva hepatitei B la nou născuţi a determinat o scădere semnificativă statistic a numărului de cazuri la vârsta 0-5 ani de la 10,72% la 5,15 % şi la vârsta 6-10 ani de la 34,98% la 21,97%.
2. În ciuda vaccinării, mai există cazuri de infecţie cronică la vârstă mică datorită deficienţelor epidemiologice reprezentate de lipsa programului de depistare a markerilor de infecţie cu VHB la femeile însărcinate şi datorită limitelor programelor de imunoprofilaxie activ-pasivă. După naştere se impune asocierea imunoglobuline specifice la vaccinare la nou-născuţii cu risc, metodă considerată standard pe plan mondial şi care ar putea controla mai eficient infecţia.
3. Interzicerea alăptării a fost mulţi ani o strategie importantă de stopare a transmisiei infecţiei.
4. Academia Americană de Pediatrie recomandă alăptarea după profilaxia pasiv-activă!
5. Seroprotecţia post vaccinală este mai bună la cei alimentaţi natural (Ac anti HBs la un an 80,9% vs. 73,2% vaccin şi 90,9% vs 90,3% vaccin plus IGVB)
6. Nu vor alăpta mamele care primesc terapie antivirală complexă.

SPONTANEOUS SHRINKAGE OF VESTIBULAR SCHWANNOMA. CASE REPORT AND REVIEW OF THE LITERATURE (Abstract): Vestibular schwannoma (VS), commonly known as acoustic neuroma, is a slow-growing, benign tumor that originates from the transition zone between the central and peripheral myelin of the vestibular branches of cranial nerve VIII. After making the diagnosis, a conservative approach is an option depending on the tumor size and involves the "watch, wait and rescan" (WWR) policy. We present a rare case of a 59 years old woman, who presented with bilateral hearing loss. Routine imaging showed both otosclerosis and a vestibular schwannoma. She was followed-up with annual MRI between 2006 and 2019 showing a complete shrinkage of the vestibular tumor. Studies describe the natural history of a vestibular schwannoma to be slow growing or in small cases spontaneous shrinkage. However, there are still no pathological theories for the tumor regression process. An internationally method of strategies based on size, radiological aspect and symptoms is needed for a standardized care by analyzing a larger series of patients.
Keywords: ACOUSTIC NEUROMA, BENIGN, SPONTANEOUS SHRINKAGE, VESTIBULAR SCHWANNOMA.

Vestibular schwannoma (VS), also known as acoustic neuroma, a tumor with the origin from the transition zone between the central and peripheral myelin of the vestibular branches of the VIIIth cranial nerve, is a slow-growing, benign tumor. It is considered to be the most frequent tumor of the cerebellopontine angle (CPA) (1).

The natural history of these tumors consists in most of the cases of continuous slow growth, followed by stagnation or even shrinkage. Upon diagnosis, the most common attitude involves its treatment through either microsurgery or radiosurgery. However, in some cases, a conservative approach is an option depending on the tumor size and involves the "watch, wait and rescan" (WWR) policy (2).

A review of the literature shows that more than a half of the tumors that are diagnosed do not grow (69%), 16% regress and from those who grow, 70% have a 2 mm/year growth (3). The mean growth rate of VS varies from 0.4 to 2.9 mm/year, and spontaneous shrinkage is observed in 3.8 percent of tumors during observation.

We present a rare case, which presented two independent causes for hearing loss, otosclerosis and vestibular schwannoma on the same side and which showed for the first time in our experience spontaneous regression on the long-term follow-up.

CASE REPORT

A 59 years old woman, after a visit at the ENT doctor because of progressive hearing loss, was recommended a head CT scan that showed that she suffered from otosclerosis. The CT imaging also revealed in the cerebellopontine angle a mass occupying lesion that was further investigated through MRI imaging.

The patient came to us with the head MRI and we concluded that she had a vestibular schwannoma in the left cerebellopontine angle.

Clinical assessment showed a good neurological condition, the cause of the bilateral hearing loss being caused by the otosclerosis.

After discussing the various types of management of this tumor, the patient decided for the "watch, wait and rescan" protocol (WWR). She was instructed to rescan the tumor once in two years or when new symptoms appeared.

The first MRI was performed in 2006, but we only have the written description. The next scan was performed in 2007 and it showed no signs of growth of the tumor with a size stationary at 6.73 mm x 11.33 mm.

Spontaneous shrinkage was confirmed in the next scan, done in 2013, as the tumor size decreased by more than 2 mm. The tumor continued to shrink. The next scan performed in 2016 and 2019, showing a tumor measuring 4.22 mm x 5.48 mm.

The tumor size was measured in coronary, sagittal and axial planes (fig. 1). No additional neurologic symptoms were present during this period. The hearing loss followed the common pattern associated with the ear pathology.

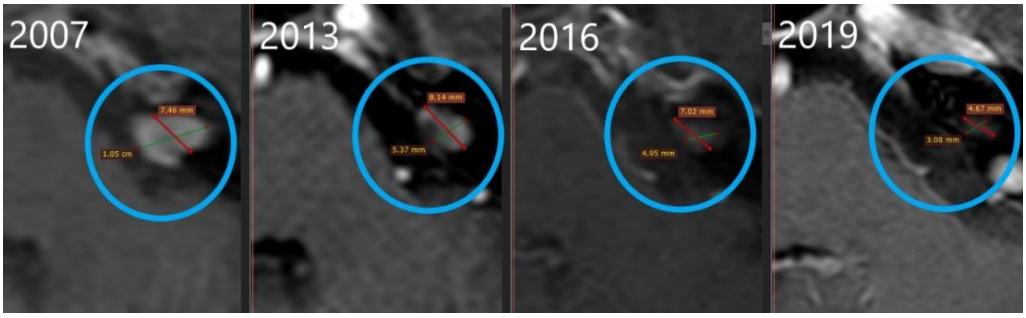

Fig. 1. Vestibular schwannoma in series of MRI with measurements showing the tumor shrinkage in axial view.

DISCUSSION

Spontaneous tumor shrinkage is a rare phenomenon but marked in the literature in some studies with follow-ups as long as 27 years (1, 2).

A review of the studies that mention tumor shrinkage in vestibular schwannoma are presented in the first table, including the current study.

In 27 reviewed studies, between 1998 and 2019, tumor shrinkage has been reported in 229 out of 4,002 patients (5.69%) with a mean follow up of 4.37 years (1-28).

As described by Huang *et al.*, 2013 a

complete regression of a VS from a 14.1 mm tumor was seen during a follow-up period of 12 years (10).

A growth-regression process was described by Yasumoto and Ito (28), in a 75-year-old patient with a right small VS that initial grew from 5.2 to 16.7 mm over 7 years, then spontaneously shrank to 8.2mm with improvement of the tinnitus, dizziness and the other initial symptoms.

TABLE I

Review of the literature – Spontaneous shrinkage of vestibular schwannoma

Author, year	No. of patients with shrinkage/total patients studied (%)	Age of patients (mean)	Mean size of tumor (mm)	mm or % of shrinkage	Follow up years (mean)
Luetjie *et al*., 1988 (13)	1/115	71	13	5,38%	5

TOTAL	229/4002	58.9			

In the largest study on the conservative management of vestibular schwannoma, Huang *et al.* (10), after observing 1261 patients, noted 48 that showed spontaneous shrinkage (4%). The approach of "watch, wait and rescan" (WWR) was analyzed by Kontorinis *et al.*, 2016 in a retrospective analysis of the medical records of 540 VS over a 15 years period, 23 (4.3%) of which demonstrating tumor shrinkage (8). Tikka T. *et al.* in 2018 achieved a direct comparison of MRI of the *internal auditory meatus* (IAM) in a group of patients with sporadic VS demonstrating spontaneous regression compared with a control group of patients with growing VS (25). In our case report the patient showed a linear tumor shrinkage during the 12 year follow up.

The study of Romani R and Pollock J, 2016 made some remarks regarding the mechanism of tumor shrinkage that is not well understood even today. They proposed environmental factors, genetic-molecular and a reduction in vascular supply hypothesis (20).

In a recent study, Lahlou G. *et al., 2018* (12) identified two specific radiologic features in a series of cases of vestibular schwannoma shrinkage. First, it's described a festooned or scalloped appearance, defined by multiple curves in the tumor outline. We found this aspect of scalloped "line" in the first MRI done in 2007, as shown in green (fig. 2).

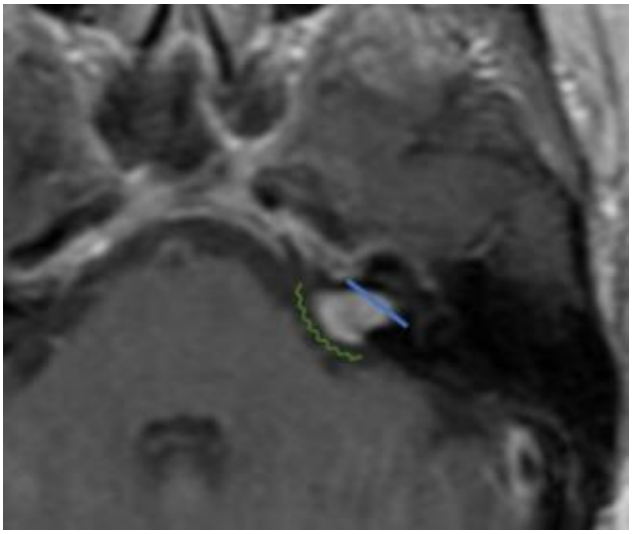

Fig. 2. Vestibular schwannoma in the first MRI:
green line – scalloped/festooned appearance, blue line – CSF infilling of the IAM

Second, on T2 weighted imaging of cerebrospinal fluid (CSF) infilling the intrameatal portion of the tumor, associated with asymmetry of the intrameatal (IAM) size. This feature was recognized in T1 weighted imaging with contrast, as displayed by the blue line, marking the CSF infilling of the IAM.

The study concluded that the two radiological features could allow neurosurgeons and neuro-otologists to easily recognize the vestibular schwannoma that will shrink spontaneous, therefore it is important to look for them and opt for a WWR protocol (12).

CONCLUSIONS

Although spontaneous shrinkage of acoustic neuroma is described as a potential natural evolution in a consistent body of literature, there are still no pathological theories for this evolution. As the genetic variations in schwannoma do not indicate a predisposition for involution, we propose a mechanism involving tumor metabolism. The failure to recruit vascularization might be, for example, an individual mechanism that can lead to tumor shrinkage (as "failure to thrive").

We argue that cases like the one we presented are a strong argument for "watch, wait and rescan" approach (WWR) towards the patients that harbor small sized tumors. The current literature endorses this policy for small or medium sized tumors, with minimal or absent symptoms. The Lahlou G. *et al.*, 2018 study provides evidence for tumor shrinkage even in large tumors (12).

An internationally standardized method of strategies based on size, radiological aspect and symptoms is needed by analyzing a larger series of patients.

NEWS

EARLY MEASLES VACCINATION AND THE IMMUNE RESPONSE

It is well known that during measles epidemics World Health Organization (WHO) recommends that the first dose of measles-containing vaccine (MCV 1) should be given at 9 months of age. But, globally, there were reported cases on infants who are too young to receive MCV1, and they remain at high risk of contracting measles. This study is the first systematic review to examine the effect of MCV1 administered to infants younger than 9 months on the immunogenicity and vaccine effectiveness of subsequent MCV doses. It was reviewed evidence of humoral and cellular immunity, including seropositivity, geometric mean titres, avidity, T-cell stimulation, and vaccine effectiveness. Their findings suggest that administering MCV1 to infants younger than 9 months followed by additional MCV doses results in high seropositivity(98%), vaccine effectiveness(95%), and T-cell responses, which are independent of the age at MCV1, supporting the vaccination of very young infants in high-risk settings. However, they also found some evidence that MCV1 administered to infants younger than 9 months resulted in lower antibody titres after one or two subsequent doses of MCV than when measles vaccination is started at age 9 months or older. The clinical and public-health relevance of this immunity blunting effect are uncertain (Lochlainn LM, de Gier B, van der Maas N, van Binnendijk R, Strebel PM, Goodman T, de Melker HE, Moss WJ, Hahné SJ. Effect of measles vaccination in infants younger than 9 months on the immune response to subsequent measles vaccine doses: a systematic review and meta-analysis. *The Lancet Infectious Diseases.* 2019 Sep 20.).

FLAVONOIDS AS PROMISING THERAPEUTIC AND DIETARY AGENTS

FLAVONOIDS AS PROMISING THERAPEUTIC AND DIETARY AGENTS (Abstract): Flavones were an essential anchor for the development of new therapeutic agents. All classes of flavonoids exhibit a variety of biological activities, but among them, flavone derivatives have been considerably explored. Numerous natural, semisynthetic and synthetic flavonoids have been synthesized and evaluated for several therapeutic activities, such as: anti-inflammatory, antimicrobial, antiallergic, antioxidant, antitumor activities. Most metabolic diseases are speculated to originate from oxidative stress and, therefore, it is significant that recent studies have shown the positive effect of flavones on diseases related to oxidative stress. In this paper, we present some fundamental elements for flavonoid therapeutic implications and future uses. **Keywords**: FLAVONOIDS, OXIDATIVE STRESS, THERAPY, PHARMACOKINETICS.

Nature has been the source of medicines for mankind since ancient times. Medicinal foods and herbal medicines, with different composition of secondary and primary metabolites, can play an essential role in the management of complex diseases. Flavonoids can be found in the human diet in fruits, vegetables, legumes, tea, dark chocolate. Some specific parts of these foods are richer in flavonoids than others, such as the peel of certain fruits (1, 2, 3).

Flavonoids are low molecular weight polyphenolic phytochemicals, derived from the secondary metabolism of plants and play an important role in different biological processes. The intake of flavonoid-containing foods may vary depending on the culinary habits of different countries. For example, soybean consumption has historically been associated with oriental crops or tea consumption is higher in countries such as the United Kingdom, Ireland or Turkey, among others. Researches in the field of flavonoids have increased since the French concept of paradox was formulated by French epidemiologists in the 1980s, i.e. a lower cardiovascular mortality rate observed in Mediterranean populations in association with the consumption of red wine and a high intake of saturated fat. Flavonoids are components of a wide variety of edible plants, fruits, vegetables and beverages such as tea, coffee, beer and wine. Thus, *in vitro* inhibition of LDL

oxidation of flavonoids derived from red wine has been demonstrated. Since then, several other beneficial properties of flavonoids have been found, as information on the mechanisms of flavonoids has been scarce (3, 4, 5, 6).

Depending on their structure, the large group of flavonoids can be divided into six categories: flavones, flavanones, flavonols, flavanol, isoflavones and anthocyanidins. Given the immense number of known flavonoid derivatives, their diversity has a direct implication on the molecular targets that have been found to represent important hubs for therapeutics. Moreover, their three-ring carbon skeleton, out of which one is heterocyclic, ensures the flexibility, rigidity and space mobility to adapt to various enzymes and receptors conformation. This is exactly why flavonoids still represent key compounds for therapy and research (5, 6, 7).

Pharmacokinetics

Most of the flavonoids are synthesized by the plants in their O-glycoside or C-glycoside forms, the aglycons being usually the storage form. Their absorption depends on the processing of the vegetal matrix and the chemical structure of each compound. Generally, flavonoids are highly metabolized in the intestine especially by β-glucosidases (acts on monoglucosides) lactase-phlorizin hydrolase (active on glucose and galactose derivatives) and, as a result, their metabolites are transported to the liver. Metabolites formed in the liver can be transported to the target cells, reenter the enterohepatic circulation through bile excretion, be hydrolyzed or excreted through urine or feces. Catechins are usually absorbed rapidly from the intestine, but dimerization leads to a decrease in their absorption. Also, trimers can be metabolized, but larger oligomers can only be transformed by the gut microbiota in the larger intestine (2, 3, 5).

Several studies have focused on improving the bioavailability of flavonoids through different approaches, such as inhibiting enzymes that limit their bioavailability, altering the composition of food matrices, or increasing the rate of dissolution. Moreover, the addition of alcohol (as wine) or proteins (milk) did not influence the absorption of flavonols and catechins (6, 8). For example, hesperidin and its aglycone (hesperetin) are two flavonoids from citrus species that have different biological properties. Hesperidin is transformed into hesperetin by the colonic microflora and it can be directly absorbed by enterocytes, is a cytochrome P450 inhibitor that is capable of affecting the metabolism of other drugs such as diltiazem, verapamil and felodipine (9).

Biologic and therapeutic potential

Flavones have antioxidant, antiproliferative, antitumor, antimicrobial, estrogenic, anti-inflammatory activity and are also used in cancer, cardiovascular disease, neurodegenerative disorders (3, 4, 7, 10, 11). Also, flavonoids affect several mammalian enzymes such as protein kinases that regulate multiple cell signaling pathways and modifications of multiple cell signaling pathways. Apigenin and luteolin are commonly found in a variety of foods such as parsley, celery, artichoke, peppers, carrots, thyme, rosemary, oregano, olive oil, peppermint, salad, pomegranate, cucumber, lemon, beet, cabbage, cauliflower, spinach, and green tea. It is well documented that luteolin acts as an antioxidant, anti-inflammatory, anticancer and inhibitor of prooxidant enzymes, both *in vitro* and *in vivo* (10, 12, 13, 14, 15).

Antioxidant potential

High levels of free radicals in living systems are capable of oxidizing biomolecules, leading to tissue damage, cell death or various diseases such as cancer, cardiovascular disease, arteriosclerosis, neuronal disorders, skin irritation and inflammation (12, 13, 16). Free radicals are highly reactive and therefore can attack membrane lipids, generating carbon radicals and producing radicals that cause lipid peroxidation. Therefore, a single radical can damage many molecules by initiating lipid peroxidation reactions. To counteract the vicious effect of free radicals, the body has several mechanisms of defence of antioxidants in the form of enzymes such as superoxide dismutase and catalase, copper and iron transport proteins, as well as water-soluble and lipid-soluble antioxidants. It has been studied that the imbalance between free radicals and the antioxidant defence mechanism is associated with several human diseases (2, 4).

Antioxidants can act by two mechanisms: preventing the initiation of oxidation or as antioxidants breaking the chain. Preventing the initiation of oxidation occurs by inhibiting the production of superoxide anions, degradation of hydrogen peroxide and chelation or reduction of metal ions, while chain-breaking antioxidants act by eliminating radicals, largely hydroxyl radicals, thus inhibiting the chain of events. Oxidative agents lead to damage of lipid membranes, proteins and DNA. Moreover, oxidative species and free radicals are involved in the pathophysiology of many diseases, such as neurodegenerative disorders, cardiovascular, cerebrovascular, autoimmune disorders such as diabetes, rheumatoid arthritis, psoriasis, etc. Therefore, different natural and synthetic antioxidants are used to eliminate free radicals (2, 3, 14).

Flavones have been reported to have a well-known antioxidant activity and can act in several ways. Therefore, flavones are significantly used in the pharmaceutical and food industry. Flavones, such as luteolin and apigenin, which contain two or three free hydroxyl groups in A / B rings, exhibit antioxidant properties at low concentrations (14, 15).

Some studies, using a QSAR model for different flavones to evaluate the correlation between the structure and the intensity of the antioxidant activity, concluded that as the number of hydroxyl groups increases, the activity is better. Moreover, two neighboring hydroxyl groups have better effects. Different flavone conjugates, such as complexes C_{60}-flavone, have been evaluated for the antioxidant potential in which the flavone phenolic fragment reacts with peroxyl radicals, while the C_{60} part of the molecule acts synergistically by trapping alkyl radicals under reduced O_2 partial pressure. Also, a natural flavone extracted from the tropical plant *Coronopus didymus* was tested for their ability to inhibit lipid peroxidation induced by γ radiation, Fe (III) and Fe (II) radiation and showed a better protective effect (4).

The 5-hydroxyl group in combination with the 4-keto and catechuic hydroxyl groups chelates catalytic active metal ions involved in redox reactions, which may prevent the formation of oxidizing species. The most harmful of the reactive oxygen species generated in the Fenton reaction is the hydroxyl radical, which can induce lipid peroxidation (fig. 1).

$$Fe^{2+} \rightarrow H_2O_2 \rightarrow Fe^{3+} + H\dot{O} + OH^-$$

$$O^{2-} + H_2O_2 \rightarrow O_2 + OH^- + \dot{H}O$$

Fig. 1. Fenton reaction

The hydroxyl groups on ring B donate the hydrogen and one electron to the hydroxyl-, peroxyl- and peroxynitrite radicals, stabilizing them, thus forming a relatively stable flavone radical (fig. 2) (4).

Other studies have shown that inflammation induced by different processes is related to cognitive dysfunction and that luteolin/apigenin treatment can effectively decrease inflammation in the brain (13, 17, 18). Some studies have also reported that the neuroprotective effect of luteolin is related to its antioxidant activity. Improvements in cognitive function due to luteolin treatment have been linked to its antioxidant activity in a streptozotocin-induced diabetes model. For example, neuronal injury and cognitive dysfunction are found in streptozotocin-induced diabetes, and chronic luteolin exposure can reduce neuronal injury and improve cognitive performance. This effect of luteolin is related to its ability to increase antioxidant activity (19, 20).

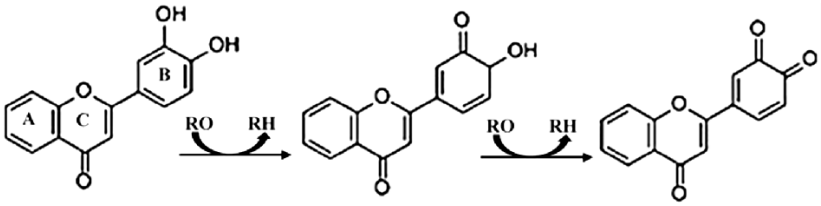

Fig. 2. Changes in the structure of 3′,4′-dihydroxyflavone
(RO – free oxidized radicals; RH – reduced radicals)

Lipid peroxidation is increased, while antioxidant enzyme activities in the cortex and hippocampus are decreased in diabetes. However, chronic luteolin treatment may alleviate such changes induced by diabetes. In addition, apigenin rich extracts have shown to reduce scopolamine-induced neuroinflammation, 1-β interleukin level, acetylcholinesterase, butyryl cholinesterase, lactate dehydrogenase and malondialdehyde activity. Moreover, the same doses (25 mg/kg and 75 mg/kg) restored the normal level of all antioxidant enzymes and the expression of the brain-derived neurotrophic factor (13, 17). These studies suggest that apigenin and luteolin may be beneficial for the prevention and treatment of neurodegenerative diseases, including Alzheimer's, due to its anti-inflammatory activity and other biological functions, including antioxidant activity (2, 5, 13, 17).

Antidiabetic potential

The apathetic lifestyle and energy-rich diet are now aggressively contributing to an astonishing increase in obesity, leading to insulin resistance, to type 2 diabetes along with retinopathy and nephropathy. Various enzymes such as α-glucosidase, aldose reductase, protein tyrosine phosphatases, protein kinase C are associated. The α-glucosidase enzyme is an intracellular enzyme involved in the breakdown of complex carbohydrates, which aids in the absorption of ingested carbohydrates, increases post-prandial blood sugar. Aldose reductase is a key enzyme in the pathway of polyol in which glucose is changed to sorbitol and its accumulation is linked to diabetic complications. It also involves the formation of advanced glycation end products (AGEs). Diabetic complications such as retinopathy, nephropathy, neuropathy are caused by an increase in the advanced

formation of glycation end products and activation of protein kinase C isomers. Among them, AGEs are known to cause ageing, as well as diabetic complications (2, 3, 20).

Numerous scientists have reported different flavone derivatives, of natural and synthetic origin, for the treatment of diabetes and its complications. In one study, various flavone 6- and 7-hydroxy flavone hybrids with aminopropanol were synthesized and evaluated as novel antidiabetic agents. Of all the synthesized hybrids only two were found to be the strongest. These active compounds possess a voluminous lipophilic substitution on ring B of flavone and smaller substituents on the nitrogen atom. Hybrids with tert-butyl and isopropylamine functionality at the N atom are of higher activity (1, 2, 3, 4, 20).

On the other hand, luteolin has inhibited the α-glucosidase enzyme up to 36% at a concentration of 0.5 mg / mL and has the potential to suppress postprandial hyperglycemia in non-insulin-dependent diabetes mellitus. 6-amino-5,7-dihydroxyflavone is a unique flavone having an amino moiety together with the usual 5,7-dihydroxyl substituents, which have been shown to be active against rat intestinal α-glucosidase. Initial studies suggested that 6-amino and 7-hydroxyl groups were essential for activity. The 5-hydroxyl substitution was favorable, while the 8-amino group was unfavorable for activity (21, 22).

Cardiovascular protective activity

It is well known that a healthy cardiovascular system has a positive impact on memory and cognition. Furthermore, most of the risk factors are determinant both for cardiovascular and brain dysfunction. Observations in regard to flavonoid-rich food intake indicated that the best benefit is in at-risk populations. Various cocoa products were administered to a wide range of people and the results indicated a decrease in blood pressure of older generation, especially in those with impaired vascular function. Nevertheless, there are still conflicting studies in which tea and other foods associated with high fat load meals could or couldn't influence the blood pressure. Therefore, further investigations are necessary to elucidate the mechanisms and the real potential of such compounds (2, 3, 6).

Several types of isoflavones such as daidzein, genistein and equol, known to induce hormone-like activity, have been observed in human trials and were noted to have a benefic effect on cardiovascular disorders and osteoporosis. Such flavonoids have shown a positive influence on various parameters associated with cardiovascular complications (atherosclerosis, platelet aggregation, lipoprotein peroxidation). A significant improvement was identified for selective extracts rich in anthocyanins. In this case, several randomized trials indicated no secondary effects and the restoration of the HDL / LDL-cholesterol balance to normal parameters (3, 6, 14).

CONCLUSIONS

Metabolic dysfunctions, cardiovascular problems and neuronal loss represent the most important lifestyle challenges for modern society. Therefore, prevention is essential and dietary choices should be made according to the nutritional and functional value of foods. Vegetable products represent a rich source of pharmacologically active compounds that could prevent ageing deficits by multiple mechanisms. Nevertheless, further research into flavonoids is a common trend that may lead to the synthesis of new therapeutic agents with great benefit for human health.

EPIDEMIOLOGY OF BURNS IN IAȘI COUNTY, A 10-YEARS STUDY (Abstract): This study intends to obtain a baseline epidemiological evaluation regarding hospitalizations for burns cases in Iași County. **Material and methods**: We performed an epidemiological descriptive study of all hospital admitted burns patients from Iași County, for a period of 10 years, from 2006 to 2015. Data used in this study originates from standard government collected information upon hospital discharge and freely available public demographic information. Statistical analysis was performed using the *Statistical Package for the Social Sciences* (*SPSS*). **Results**: There were a total of 3,065 residents of Iași County hospitalized for burn-related causes in the studied period. Monthly distribution showed an average of 25.5 cases, with peaks in December (30.3 cases/month) and July (29.1 cases/month). Males represented 56% of cases and Male to female Ratio period was 1.27:1. The urban/rural proportion averaged 1:1.55. Average length of stay had a mean value of 9.79 days, while average median length of stay was 7.5 days. A total of 106 deaths were reported. Mortality expressed as deaths-to-cases ratio resulted in 3.54% for the overall period. **Conclusions**: This is the first study upon the epidemiology of burns in Romania in the last 30 years. The studied group presents a strong rural predominance with an increasing trend, and a decrease of annual case numbers combined with an increase in burn-related deaths. Quality of collected data is critical towards a precise overview and specific indicators are needed in reporting burns. **Keywords**: BURNS, EPIDEMIOLOGY, BURN DEATHS, BURN REGISTRY.

Burns represent a common cause of injury and often generate socio-economical losses as a result of disability or death. Decades of experience have shown that a highly coordinated and complex system is needed to manage these kinds of lesions, ensuring the best possible outcomes. Reliable data is paramount in planning such burns management systems and strong epidemiological studies are the foundation of a successful early stage.

Although data is collected from every hospital in Romania after a patient is discharged and burns patients are no exception to this rule, up to this day there has been no report upon annual number of burns, their severity, burn-related deaths or outcomes.

The amplitude of burn care and the necessity of proper burn management systems have periodically occupied the spotlight in Romania during recent years. Ever since the Colectiv night club fire, a mass casualty

disaster in 2015 which claimed the lives of 65 young persons, severe burns often are the subject of media debate. This has steered Romanian politicians towards promising important changes in burn care, most notably building burn centers, but very few changes have actually been implemented to this day.

The purpose of this study is to have a baseline view upon the epidemiology of burns in the second most populous county in Romania, to hopefully provide guidance towards obtaining national epidemiological data.

MATERIAL AND METHODS

This is an epidemiological descriptive study of all hospital admitted burns patients from Iași County, for a period of 10 years, from 2006 to 2015. Included were all patients residing in Iași County, indifferently of where in Romania they received the medical treatment.

Data included in this study was kindly provided by the National School of Public Health, Management and Professional Development, Bucharest (NSPHMPDB) and reflects standard government collected information upon hospital discharge. The analyzed dataset includes following information: main discharge ICD code, urban/rural residence, sex of patient, month of discharge, death (if it occurred), length of stay, mean and median length of stay, patient age category (under 1 year old, 2-4 years, 5-9 years, 10-15 years, 16-19 years, 20-29 years, 30-39 years, 40-49 years, 60-69 years, 70-79 years and over 80 years old).

Demographic data was acquired via TEMPO statistics platform, National Statistics Institute (1). Only residents of Iași County were considered, in the specified timeframe. Total population number, age groups, sex and urban/rural provenience were considered for this study.

Statistical analysis was performed using the *Statistical Package for the Social Sciences* (*SPSS*) software, IBM Corporation (IBM® SPSS® Statistics 25).

RESULTS

There were a total of 3,065 cases of burns patients in the studied period. The year with the highest number of cases was 2012, while the lowest number of cases was reported in 2008. Monthly distribution showed an average of 25.5 cases, with peaks in December (30.3 cases/month), July (29.1 cases/month), followed by November and September (27.4 and 26.3 cases/month).

The incidence of hospitalized burn cases for residents of Iași County was 40.38/100.000 persons. Overall, males represented 56% of cases and female only 44%. Male to female ratio in the whole period was 1.27:1 with a maximum of 1.63 in 2010 and a minimum of 1.05 in 2012. The urban/rural proportion was on average 1:1.55, with a maximum of 1:1.84 in 2008 and a minimum of 1:1.31 in 2012.

Average length of stay varied between 7.56 days in 2011 to 11.61 days in 2009, with a mean value of 9.79 days. Meanwhile, average median length of stay was 7.5 days, with a minimum of 6.93 days in 2008 and a maximum of 8.23 days in 2012.

A total of 106 deaths were reported, with a maximum of 14 deaths/year in 2007 and a minimum of 7 deaths/year in 2011, averaging 10.6 deaths/year. Thus, mortality expressed as deaths-to-cases ratio resulted in 3.54% for the overall period, with a minimum of 2.58% in 2010 and a maximum of 3.9% in 2012. Proportionate mortality for burn cases was an average of 1.26 burn deaths for every per 1000 overall

deaths in Iași County, varying from a minimum of 0.85/1,000 to a maximum of 1.75/1,000.

DISCUSSION

This is the first study on the epidemiology of burns in Iași County and the only such research in the last 30 years in Romania. It is highly reliant on collected data type and quality, resulting in a limited insight in burn severity, survival, reconstructive procedures and long-term outcomes. Also, it only considers discharged cases, as Emergency Department visits, outpatient cases and out-of-hospital deaths are not collected into the same database.

Furthermore, data collection based on discharge documents yields unusable clinical information, as ICD coding is used to report cases. For a quality burns database, the total body surface area of the burn, its degree, anatomical location and etiology are needed. Unfortunately, ICD coding is structured in such a manner that it cannot provide all these data simultaneously, resulting in limited and often truncated clinical information, rendering quality of care studies virtually impossible.

In spite of these limitations, the study exposes important epidemiological data, upon which public health strategies, prevention programs and policy changes can be based upon.

The annual number of hospitalized burn cases shows an overall downward trend, when the whole 10-year period is analyzed. Meanwhile, the total population of Iași County has shown a steady increase, from 853,392 to 916,599 people. Upon first look, this evolution would seem normal in an upper medium income country, member of the European Union, as this decrease in number of burn cases is observed worldwide in such countries. But upon closer inspection, the studied timeframe presents two contrasting periods: a smooth descent in the case numbers curve between 2006 and 2012, followed by a steep rise in 2013, 2014 and 2015. Further analysis of the following years would be interesting in discovering if the trend has indeed reversed and the number of burns cases is increasing.

One of the interesting results is the disparity between the urban-to-rural ratio in the normal population of Iași County and this ratio in the hospitalized burns patients. While in the general population the urban-to-rural ratio averaged 1:0.93 in the analyzed period, this ratio was 40% higher in our studied cases. Moreover, while in the general population of the county this ratio has a decreasing trend, in the burns population it shows an opposite forecast. Considering that the North-East region of Romania is one of the poorest in the European Union, rural areas generally present lower socio-economic indicators and that Iași city is one of the fastest growing hubs of Romania highly driving urbanization through polarization, it seems this disparity will only accentuate with time. An expanding gap could widen, leaving vulnerable population increasingly exposed to events resulting in burn injury unless preventative measures are taken.

Concerning the monthly distribution of burn cases, the observed periods of high afflux follow previously described patterns: a summer peak where usually flame burns occur, and a high plateau during the colder months, where burn etiology is more often related to residential heating and scalding. Quite particular in this geographic region are the flame burns during the beginning of the cold period, resulting from the use of combustion accelerants in stove heaters,

followed by residential fires caused by improvised heating devices. Including burn etiology in the collected data from burns patients would allow precise measurement of the impact on healthcare of each specific cause, enabling tailored prevention programs to be implemented.

Gender distribution showed that males were more frequently burned in each year of the studied period. However, the evolution of the number of male burns cases shows a clear decreasing curve, while the evolution of female burns cases almost is stationary during the studied timeframe. Interestingly, the number of female burns cases follows the same decreasing pattern as the males up to the year 2011, where it reaches a minimum from where it starts a steep ascent in 2013, 2014 and 2015, bringing the male-to-female ratio closer, to 1.1:1. It would be interesting to see if this evolution continues in the same manner and the male-to-female ratio of burns cases will reverse in following years. Also, proper research into burn etiology in women might uncover causes which can be tackled through specific measures, thus reducing overall burn burden.

The evolution of the average length of hospital stay contrasts to the one of the median length of stay: while the former has a slight tendency to decrease, the latter has an opposite increasing trend. While conclusions upon the dynamic of length of stay cannot be drawn, knowledge of this data is a useful planning instrument for healthcare policy developers. More precise studies are needed to clarify length of stay evolution, but other qualitative tools (such as severity indexes) are required for refined answers.

Annual number of deaths of hospitalized burns patients showed a slight expansion, contrary to the trend of case numbers (fig. 1) and international trends. More so, it had the same contrasting segments: an initial steep downwards curve from the beginning of the studied period to a minimum of annual death-related burns in 2011, followed by a similarly, but opposite, steep growth from 2012 to the end of the studied period. Although the number of annual deaths from all causes in Iași County increased each year, proportionate mortality for the burns cases followed an almost identical pattern and its evolution graph is almost identical to the total number of burn-related deaths in hospitalized patients in the studied timeframe. Two different events might be accountable towards an impact on the quality of care in that period: the issue of Health Minister's order (2) concerning transfer of severe burns to facilities in Bucharest and the fact that the only specialized adult burn treatment facility in the County suffered a relocation from where it had uninterruptedly functioned for the previous 25 years to an improperly designed temporary location. Separate studies should be conducted to evaluate the impact of each event.

The average deaths-to-cases ratio representing in-hospital mortality for burns is higher than those found in Taiwan (1.5%) (3), France (2.5%) (4), Norway (2.1%) (5) or the Netherlands (3.2%) (6) in similar years, but lower than the one in Portugal (4.4%) (7) and corresponding to the ones found in China (varying from 0.3% to 7.5%) (8). Data regarding burn-related deaths in Iași County should be however regarded with caution, as it originates from all types of hospitals (primary, secondary and tertiary), in a region with no burn centers, which has traditionally been a referral area for this pathology from neighboring counties but suffered major organizational transitions in the studied period.

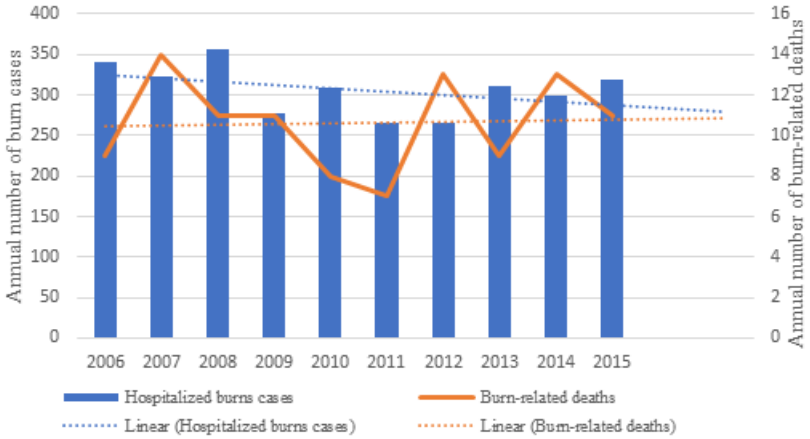

Fig. 1. Evolution of annual numbers of burn cases and deaths, between 2006 and 2015, in Iași County

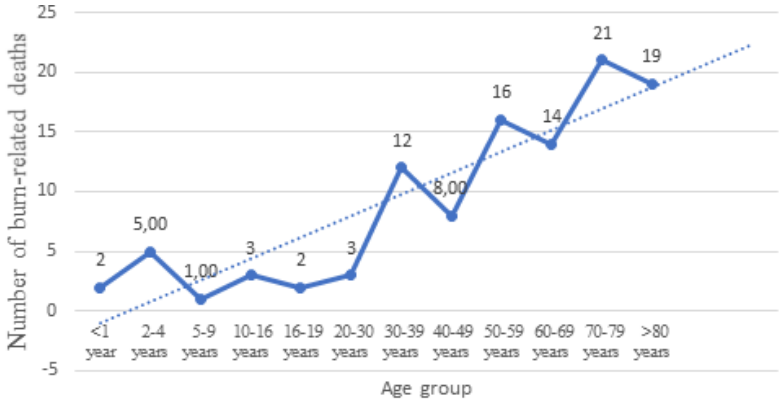

Fig. 2. Distribution of burn-related deaths according to age group, between 2006-2015, in Iași County

Males account for 59% of burn deaths, a higher percentage than in the number of burn cases. This would suggest that males are more susceptible to dying following a burn, but to properly investigate such a claim more precise studies should be performed, to match for burn etiology, size, depth and patient characteristics.

Analysis on the age distribution of burn deaths has been performed and the results show that there is an exponential increase in deaths as age grows (fig. 2). Children under 16 represented only 10.3% of total burns deaths, while adults over 60 accounted for 50.9% of cases. While there are separate facilities in Iași for the care of pediatric and adult burn patients and their results should be evaluated separately, our findings reflect international patterns: children tend to recover better from burns and there are rare cases of pediatric deaths caused by burns, while geriatric patients usually have a higher rate of complications and mortality.

It should be noted that there is a significant number of burn-related deaths which are unaccounted for and evade this statistic, due to the fact that persons who die before reaching the hospital are transported directly to the Legal Medicine Institute of Iași (9). These methods of separate reporting adversely affect the chances of obtaining an accurate image of the burden burns impose on the healthcare system.

CONCLUSIONS

This is the first study upon the epidemiology of burns in Romania in the last 30 years. In the ten-year period studied there has been an annual average of 306.5 burn cases, 10.6 deaths and 3.5% in-hospital mortality. There was a male predominance in case numbers and especially in burn-related deaths. A predominant rural provenience was noted, with an increasing trend. Although annual number of burns cases has been declining, mortality showed a slowly increasing trend line.

Such epidemiological studies provide the foundation upon which lay prevention programs, healthcare policies and government strategies. To this respect, they are indispensable to a nation. However, quality of collected data is critical towards a precise overview. We suggest adding quality criteria (etiology, burn size, depth, location) to government collected data concerning burn patients, preferably in the form of a national burn registry.

ACKNOWLEDGEMENTS

RENAL COLIC IN PREGNANCY (Abstract): Renal colic in pregnant women is a serious condition, mainly when is associated with fever. **Material and method**: Our retro-prospective study analyzes 111 cases managed conservatively or with endourological procedures for renal colic – insertion of JJ stents and percutaneous nephrostomy. **Results**: Clinical evolution determined the insertion of JJ stents in 60 cases and the failure of this procedure imposed percutaneous nephrostomy in 5 cases. In 56 cases urinary tract infection was associated and in 2 cases, despite all efforts, the patients deceased due to sever sepsis. **Conclusions**: The immediate drainage of the upper urinary tract for renal colic in pregnancy is the recommended treatment, especially when the pain is associated with fever. JJ stens were well tolerated, even when they were replaced after 3 months. Pregnant women with a history of UTI or stone disease should be carefully followed-up. **Key words**: RENAL COLIC, PREGNANCY, HYDRONEPHROSIS, URINARY STONES, JJ STENTS

MYOFUNCTIONAL TREATMENT OF OPEN BITE IN A PATIENT WHO SUFFERED FROM RECURRENT LINGUAL HAMARTOMA. CASE REPORT

MYOFUNCTIONAL TREATMENT OF OPEN BITE IN A PATIENT WHO SUFFERED FROM RECURRENT LINGUAL HAMARTOMA. CASE REPORT (Abstract): Hamartomas are defined as an overgrowth of improper proportions of tissues indigenous to the anatomic area of occurrence. Hamartomas may occur in any organ of the body and are common in the spleen, liver, kidneys, lungs and pancreas. However, hamartomas of the tongue are extremely rare. The present article aims to present the progress of orthodontic treatment for open bite following tongue enlargement due to recurrent hamartoma in a healthy 7-year-old girl. Multidisciplinary periodontal, pedodontological, and then orthodontic treatment was planned. The patient received a myofunctional device to correct the position of the tongue and to control open frontal occlusion during the eruption of permanent teeth. After 6 months, the patient was reassessed and the maxilla expansion, occlusal status and tongue interposition were improved. **Keywords**: MYOFUNCTIONAL APPLIANCE, OPEN BITE, TONGUE HAMARTOMA.

Myofunctional appliances have been used for many years. There is a definite place for these appliances in orthodontics today because they are simple and economical, but the cases need to be carefully selected, and the operator needs to be well trained in their use (1).

Open bite is considered one of the most challenging malocclusion and its treatment must improve occlusion and oral function producing a satisfactory and stable result. As open bite treatment in adults may frequently require surgical procedures, and malocclusion may lead to the development of temporomandibular disorder (TMD), the earlier this malocclusion is corrected, the better the prognosis will be (2).

The term hamartoma is used to describe a nonneoplastic, abnormal, and haphazard overgrowth of conglomerates of mature cells and tissues indigenous to the anatomic site from which it occurs, often with one predominating element (3, 4). This tumor-like malformation is benign, and most hamartomas are located in the liver, spleen, pancreas, and kidneys (5). However, hamartomas of the tongue are extremely rare (5).

Therefore, the aim of this case report is to present the progress of orthodontic treatment (myofunctional appliance) for open bite following tongue enlargement due to recurrent hamartoma in a healthy 7-year-old girl.

CASE REPORT

A 7-year-old female patient presented to the orthodontic clinic because of aesthetic changes to the incisors (multiple spaces between the teeth). Her medical history revealed that she underwent three surgeries of a recurrent lingual hamartoma.

Extraoral examination revealed the following features: leptoprosopic facial type, enlarged lower face, and reversed lips with short upper lip (fig. 1).

The facial profile was markedly convex. When the patient closed the mouth, the teeth were not visible and there was some degree of lip incompetence. In addition to these dentofacial deformities, there were complex occlusal changes. The patient also reported major functional disturbances: tongue interposition and chewing difficulties.

Intraoral examination revealed moderate oral hygiene and mixed dentition with the following changes: treated and untreated dental lesions, dentoalveolar class II/1 Angle anomaly, anterior open bite canine to canine, bilateral reverse occlusion due to maxillary deficiency, and spaced dentition on the upper and lower arches (fig. 2).

Fig. 1. Extraoral examination

Fig. 2. Intraoral examination

A panoramic radiograph revealed a dentoalveolar disharmony with spacing, and multiple treated and untreated dental lesions (fig. 3).

Cephalometric analysis showed a Class I pattern (ANB, 4°; mean, 0°-4°), although the SNA angle of 77° (mean 82° ± 2°) and the SNB angle of 73° (mean 80° ± 2°) showed a retrognathic condition. The mandibular plane angle was steep with an enlarged gonial angle Sn/GoGn° of 43° (mean 30°± 2°). The upper and lower incisors were buccally inclined +1/Na of 34° (mean 22°) and -1/NB of 29° (mean 25°) (fig. 4).

Fig. 3. Orthopantomography

Fig. 4. Cephalometric analysis

The *treatment objectives* were to (1) improve the patient's oral hygiene and periodontal health, (2) treat the dental lesions, (3) correct the tongue interposition, (4) expand the maxilla, (5) align the arches, (6) close the anterior open bite, (7) correct incisor tipping, and (8) develop ideal overjet and overbite.

Treatment plan. Multidisciplinary, periodontal and pedodontic treatment was carried out. After the improvement of oral hygiene, and treatment of dental lesions, the patient received a myofunctional device, Myobrace for Kids™ -K1 (The Myobrace System ®, Myofunctional Research Co, Australia), to correct tongue position and control the frontal open bite during eruption of permanent teeth (fig. 5). The patient was advised to wear the appliance 1-2 hours during the day and all night to be effective, as recommended by the manufacturer.

Fig. 5. Myobrace for Kids™ -K1

Treatment progress. Patient compliance and cooperation were good. The frequency of follow-up visits was every 2 months, until the eruption of permanent teeth. After 6 months, the patient was reassessed and the maxillary expansion, occlusal status, and tongue interposition were improved (fig. 6). The parents were informed that, depending on the growth pattern, an additional fixed orthodontic treatment with frequent visits and good cooperation will be necessary.

Fig. 6. Treatment progress at 6 months

DISCUSSION

Open bite is recommended to be treated as soon as it is diagnosed. This malocclusion results from an interaction between various etiological factors including bad oral habits, mouth breathing, muscular dysfunctions and skeletal abnormalities (2).

In our case, tongue enlargement due to the recurrent hamartoma determined its interposition between the dental arches, causing the opening of frontal occlusion.

This paper reports a case of open bite associated with posterior crossbite which was treated with a myofunctional appliance. This approach permitted to close the open bite by controlling tongue interposition. Using this appliance also corrected the posterior bilateral crossbite mainly caused by occlusal interference. Thus, the goal of treating this type of malocclusion must be to reinstate an ideal occlusion, improve oral and breathing functions, and properly reestablish normal muscular activity in the mastication, facial and tongue muscles.

Myobrace for Kids™ - K1 (Myofunctional Research Co, Australia) provides habit correction and is made of flexible silicone to adapt to any arch-form and poorly-aligned teeth. Its flexible nature also means that it offers improved retention for night-time use.

This type of functional appliance changes the posture of the mandible into a forward position, and stimulates transverse development, by skeletal and dental improvement in Class II malocclusion (6).

The trainer and similar appliances are claimed to encourage transverse bone growth by acting as a “shield” for the cheeks and bring about muscular relaxation and protection of the teeth and articulations from bruxism, by virtue of the “bite effect” (7, 8). The trainer is claimed to correct a skeletal Class II by an active mandibular force. By distancing the lower lips from the dental alveolar arch, the trainer is claimed to prevent the malposition of the tongue and lower lip during swallowing, thus solving the associated dental open bite (1).

Quadrelli et *al.* recommended this appliance to correct the interposition of lips between dental arches, atypical swallow-

ing, and the centripetal thrust of cheeks upon the dental arches; to discourage oral respiration; to avoid bruxism; and to favor the action of the external pterygoid and thus encourage the active push of the mandible (9-10).

Orthodontic intervention with the eruption guidance appliance in the early mixed dentition is an effective treatment modality for malocclusions with Class II or Class II tendency, excess overjet, deep bite, open bite, crowding, anterior crossbite, or buccal crossbite. During the treatment, the erupting permanent incisors and first molars were guided into their correct positions in the dental arches (11).

Usumez *et al.* (1) reported that this kind of appliances modifies the inclination of both upper and lower incisors. In this case, incisor inclinations were improved in both dental arches bringing their values closer to normal. It may be hypothesized that during the course of treatment the Myobrace for Kids™ - K1 caused positioning of the incisors changing their inclinations, which stimulated modeling of the whole dentoalveolar units (12).

Myobrace for Kids™ , used by the patient during a couple of hours during the day and overnight, was fully accepted with no complaints, and successfully corrected the crossbite, closed the open bite, and discouraged the interposition of the tongue. Therefore, it seems that getting good patient compliance with functional appliances may be more related to the ability of the professional to motivate and encourage the patient to use the appliance than the discomfort, pain, or speech difficulties associated with those orthodontic techniques (13-15).

CONCLUSIONS

Our study shows that although lingual hamartoma is quite rare it can cause major changes in the dentomaxillary apparatus and implicitly in occlusion.

Early functional treatment can correct occlusal changes over time if we cooperate well with the patient.

NEWS

THE EFFECTIVENESS OF HORMONAL TREATMENT IN PREVENTING ENDOMETRIOSIS RECURRENCE AND IMPROVING WOMEN'S CLINICAL SYMPTOMS AND QUALITY OF LIVE

An observational cross-sectional study was conducted on 185 patients with endometriosis to evaluate the effects of hormonal medical treatment (progestin, GnRh analogs or continuous oral contraceptives) and establish the endometriosis recurrence, the current clinical symptoms and the influence on the quality of life. The group of study consisted in women of reproductive age and they were devised into three groups of patients: Group A (n=34) women who did not undergo hormonal treatment neither before nor after the first endometriosis surgery, Group B (n=76) women undergoing hormonal treatment after the first endometriosis surgery and Group C (n=75) women undergoing hormonal treatment both before and after the first endometriosis surgery. The women have been followed up for at least 2 years after the first endometriosis surgery. The duration of medical treatment was of minimum 12 months before surgery and at least two years after surgery. The results showed a lower rate of endometriosis reoperation and a lower rate of dysmenorrhea among the group C of patients. The study concluded that hormonal treatments represent a valid cornerstone of endometriosis management and it may be useful as alternative to surgery, but also before surgery for a better planning and after surgery in order to reduce the risk of recurrence (Tommaso Capezzuoli, Silvia Vannuccini, Daniele Mautone, Flavia Sorbi, Huixi Chen, Fernando M.Reis, Marcello Ceccaroni, Felice Petraglia. Long-term hormonal treatment reduces repetitive surgery for endometriosis recurrence. Available online 22 September 2020., https://doi.org/10.1016/j.rbmo.2020.09.018).

ASSESSING THE OPINION OF SENIOR STUDENTS ABOUT DENTAL EDUCATION DURING THE PANDEMIC PERIOD

ASSESSING THE OPINION OF SENIOR STUDENTS ABOUT DENTAL EDUCATION DURING PANDEMIC PERIOD (Abstract): During the pandemic period, many universities reorganized their way of teaching, practicing, and interacting with students. Theoretical and clinical activities were conducted online. **The aim** of the present study is to identify the opinion of senior dentistry students about online activities. **Material and methods:** An online questionnaire was distributed to senior dentistry students enrolled in the Faculty of Medicine and Pharmacy, University of Oradea. In total, 69 respondents were included in the research. Information regarding socio-demographic data, self-reported health status, online activity schedule, and satisfaction with practical and theoretical activity was gathered. Data were analyzed using *SPSS version 23*. **Results:** 49 female and 20 male students, average 25 ± 2.15 (minimum 23 and maximum 35 years old) declared that they sustained only online activities. Most of them connect to online classes from their homes, with 59.42% using laptops and 34.78% connecting from smartphones. Almost half (47.33%) never use video connection in their online classes. Many of them (95.65%) use social media to communicate with colleagues and half of the number of students use the university platform to communicate with their academic teachers. 80% of students preferred practical activities in classrooms and more than 1/3 of respondents considered that there is knowledge that cannot be taught online. The behavior during online classes and the opinion of students regarding the online activity are also presented. **Conclusions:** Despite the present results, there is little evidence about the impact of online medical education on student formation and knowledge. Using their experience as students, seniors do not appreciate online teaching as a consistent option. **Keywords**: DENTISTRY, COVID 19, EDUCATION, STUDENTS, HEALTH, PANDEMIC, UNIVERSITY.

With the advent of the new Coronavirus, the entire world is facing the greatest public health challenge of the 21st century. Although from Spanish Influenza to the present times there have been other viruses that caused acute respiratory syndromes, such as H1N1 in 2009, MERS in 2012 or ZIKA and EBOLA in 2016, none of them had the ability to transmit so rapidly from person to person nor to kill especially the

elderly or people with various comorbidities.

Since its appearance in December 2019 in Wuhan Province, China and until now, SARS COV 2 has infected over 55 million people globally, out of whom 1.34 million have died. (1) Although it was initially thought that the range was only limited, as China took all the measures to limit transmission, because of the migration between countries and continents and due to the ease with which it is transmitted, an explosion occurred in the early 2020 regarding the number of cases and deaths worldwide, which led to the declaration of the SARS COV2 infection wave by the World Health Organization as a global pandemic in March 2020. (2)

In order to try to stop or at least reduce the spread of the disease, in several countries of the world, including Romania, states of emergency or alert have been established leading to restrictive measures by limiting all economic, social, and human activities. This lockdown produced, in addition to affecting the socio-economic environment, a direct problem facing the education system because of the school closures.

Consequently, online teaching has become part of the education system around the world and has taken many countries by storm since there was not sufficient time to adapt to the new teaching style, because everybody was accustomed to traditional, face-to-face teaching and lacked the necessary infrastructure and skills to teach exclusively online. This has, in turn, made it difficult for both students and teachers and affected the educational activity as a whole. These drawbacks in teaching will lead to educational deficiencies in time, and they will be difficult to correct and will implicitly affect the quality of life both socially and economically.

During the lockdown imposed by the COVID-19 pandemic crisis, many European dental schools were rethinking the way they organize their activity of teaching and interacting with students. The face-to-face activities were interrupted, and clinical activities suffered a transition towards the e-teaching processes. Some universities have switched from classroom to virtual activity more easily, and the challenges have been on the part of both academics and students.

During the first months of restrictions, most students returned to their homes. The internet was a powerful resource for reaching millions of students in different geographical regions and the only tool to continue their medical education. As such, it was a great opportunity for dental students and university teachers to build and retain the theoretical and clinical practice through many educational instruments. (3, 4) Also, in a recent survey conducted by Quinn *et al* (5) data were published regarding the immediate changes in the management of dental schools in some European countries: 90% of dental schools reported using online pedagogical software tools, 72% used live or streamed videos, 48% provided links to further online materials while 65% participated in organizing virtual meetings in order to provide more options for students and teachers. Also, data about small working groups and social medical groups were gathered.

Dental students had to face a double wave of stress: on the one hand, it was the fight against the consequences of social distancing and self-isolation (related to the increased rates of depression, anxiety, and fear of infection) and, on the other hand,

the stress of rapidly adjusting to the new way of learning, studying, and being evaluated, as their medical education had to continue in the new framework.

The present study is the first one undertaken in Romania among dentistry students and describes the opinion of senior students. Among all academic years, seniors are more prone to compare different styles of teaching and tools and to identify the strengths and limitations of online teaching and evaluation. The results presented in this paper are part of a larger piece of research work that include dentistry students from all years of study and from many universities.

MATERIAL AND METHODS

Participants and instruments

The study was developed during the last weeks of November 2020. An online questionnaire was distributed among senior medical students from Faculty of Medicine and Pharmacy, Dentistry specialization, University of Oradea, Romania, using *Google Forms*. Students had to answer a succession of items collecting information about their socio-demographic data (age, gender, environment, living conditions, accommodation etc.), medical data related to their health in the last six months (the presence of chronic disease, being under medical treatment, feeling depressed, anxious, bored or having a sleep or appetite disorder), academic activity (online participation, platforms used for didactic activity, their level of satisfaction with the results obtained and with their level of knowledge etc.).

The link to the questionnaire was sent to all senior students by the administrator of the Faculty. All the items were mandatory. The inclusion criteria considered only questionnaires filled in before the deadline.

Ethical approval

The study was approved by ethical committee of the University of Oradea, No.12/20.11.2020. The students were informed about the purpose of the study, the confidentiality of collected data and the fact that they could withdraw from the research with no consequences.

Statistical analysis of data

Collected data was analyzed using IBM *SPSS Statistics, version 23*. For descriptive analysis we calculated means, standard deviations, and frequencies. For comparative analysis we performed Mann–Whitney rank statistic tests to detect and describe significant differences between qualitative variables. The correlation analysis of the data was done using Spearman correlation; a $p < 0.05$ was considered significant.

RESULTS

Socio-demographic and self-reported health-related data

All 69 participants to the research (49 females and 20 males, average 25 ± 2.15, minimum 23 and maximum 35 years old) were enrolled in the final year of study in the University of Oradea, Faculty of Medicine and Pharmacy – Dentistry specialization. The total number of enrolled students is 70, so the response rate was 99.9%.

Most of the participants come from urban and rural areas – counties from Central and Western parts of the country (32 from Bihor, 13 from Cluj, 4 from Salaj, 3 from Suceava, 3 from Alba, 3 from Maramures, 2 from Satu-Mare, 1 from Bistrita, 1 from Brasov, 1 from Bucharest, 1 from Hunedoara, 1 from Mures) and 1 international student. 1/5 of respondents were from rural areas (N = 14, 20.29%),

During the academic year, almost half of them lived by themselves (N = 31,

44.93%), 1/3 with their parents (N = 19, 27.54%), some shared an apartment (N = 18, 26.09%) and only 1 student lived on campus.

More than 1/3 stated that they were smokers (N = 26, 37.68%), 23 (33.33%) were drinking alcohol and 8 (11.59%) used energy drinks, while 2 students declared that they sometimes consume illegal drugs. Several students (N = 7, 10.14%) declared that they have a chronic disease.

Students were asked if they were suspected or confirmed of being infected with COVID 19 - 20 students (28.99%) had been in contact with infected persons with COVID 19 and only 2 were later confirmed of having been infected.

Students had to rate the level of satisfaction with their physical and mental health during the last months of social distance and restrictions related to the pandemic period. The answers were distributed on a 5-points Likert scale from 1 (*totally unsatisfied*) to 5 (*totally satisfied*) (tab. I).

TABLE I

Satisfaction with their physical and mental health during the pandemic

Items	Mean ± SD*
*How satisfied are you with your **physical health** during the restrictions related to the COVID 19 pandemic?*	3.59 ± 1.129
*How satisfied are you with your **mental health** during the restrictions related to the COVID 19 pandemic?*	3.23 ± 1.139

*Mean and standard deviation (M ±) and N (%)

Living for a long period of time inside their homes, houses or rented appartements in the city or on campus determined a lot of changes in their daily lifestyle, particularly related to sleeping and eating behavior and mood. Students were asked to identify if, in the last 6 months, they had experienced sleep or appetite disorders, if they felt depressed, anxious, or bored (tab. II).

TABLE II

Self-rated health

Items	Mean ±SD *
I noticed that during the pandemic, I had sleep disorders	2.58 ± 1.355
I noticed that during the pandemic, I had appetite disorders	2.17 ± 1.414
I noticed that during the pandemic, I felt more anxious	2.77 ± 1.238
I noticed that during the pandemic, I felt more depressed	2.75 ± 1.218
I noticed that during the pandemic, I felt more bored	3.22 ± 1.571

*Mean and standard deviation (M ±) and N (%)

Social relationship and daily activity

Because of the social distancing and, for some of them, the impossibility to see their families due to the travel restrictions, some students felt isolated and lonely. Part of the students returned to their homes, but others had to shelter in their rented apartments or on campus. Social activities were

restrained. Some items questioned students about their level of satisfaction regarding the relationship with family members, colleagues, and friends (tab. III).

During the present pandemic period, online activities forced students to stay inside and to find leisure activities adapted to this situation. Among the most frequent activities that students mention that they have in their free time are cooking (21.7%), reading books (21.7%), watching movies or documentaries (23.2%) and physical activity (10.1%).

TABLE III

Satisfaction with relationship

Items	Mean ± SD*
*How satisfied are you with your relationships with **friends** during the restrictions related to the COVID 19 pandemic?*	2.91 ± 1.210
*How satisfied are you with your relationships with **family members** during the restrictions related to the COVID 19 pandemic?*	3.65 ± 1.293
*How satisfied are you with your relationships with **colleagues** during the restrictions related to the COVID 19 pandemic?*	2.84 ± 1.346

*Mean and standard deviation (M ±) and N (%)

Fear of infection with COVID 19

The fear of becoming infected with COVID 19 was also measured. During practical stages, students are usually in close contact with their colleagues and patients. Among the medical specialties, dentistry is evaluated as having a high risk of infection (with students and dentists being in contact with salivary and blood compounds and exposed to aerosols) (tab. IV).

TABLE IV

Fear of becoming infected with COVID 19

Items	Mean ± SD *
I am afraid that I may become infected with COVID 19 during practical activities at the faculty	3.78 ± 1.371
I am afraid that I may become infected with COVID 19 from patients I meet during internships.	3.84 ± 1.400
I am afraid that I may become infected with COVID 19 from colleagues I meet during practical stages and lectures.	4.09 ± 1.337

*Mean and standard deviation (M ±) and N (%)

Theoretical and practical activity during pandemic period

Immediately after the lockdown, dental schools continued to have online activities and teaching and evaluation were all conducted online. Students were asked *how satisfied they were with the academic results during the restrictions imposed by COVID 19 pandemic*. The answers ranged from 1 (*totally unsatisfied*) to 5 (*totally satisfied*), with the following frequencies: 11.6%, 15.9%, 21.7%, 33.3% and 17.4% respectively.

More than 50% of students stated that their practical training suffered due to the exclusive online activity. Similarly, while

31% agree with the fact that lectures are more interesting online, only 13% believed that the same was true when it comes to the practical stages. From all questioned students, 1/3 stated that their time allocated for individual training increased considerably and 1/3 of respondents considered that there is knowledge that cannot be taught online, with practical stages being mandatory for some disciplines.

Some items wanted to identify the way students attended their online classes and what their most common behavior was (tab. V).

TABLE V
Students' opinion about online activity

Items	Mean ± SD *
I always attended the course / lab in its entirety when I connected online	4.14 ± 1.033
The amount of information taught during online activity is higher	3.13 ± 1.110
I believe that online teaching is as effective as institutional teaching	3.10 ± 1.426
During online activity I prefer to stay connected through video	2.03 ± 1.248
Online student assessment is more objective than face-to-face assessment at school.	3.05 ± 1.290
I believe that exclusive online assessment of students encourages unethical behaviors	2.68 ± 1.266

*Mean and standard deviation (M ±) and N (%)

Comparative analysis

Significant differences depending on the gender of the participants were identified only in an item aimed at reporting health-related data. Thus, a higher score was identified for men (Mean rank = 37.45), compared to women (Mean rank = 34.00), in terms of drug use ($p = 0.026$).

Regarding the comparative analysis based on the students' residential environment, the *Mann-Whitney U Tests* revealed that there is a significant difference between participants identified for the variables of communication with teachers ($p = 0.012$) and cigarette consumption ($p = 0.045$). Higher scores on these variables were obtained by participants from rural areas (Mean rank = 46.14, respectively Mean rank = 43.07), compared to those from urban areas (Mean rank = 32.16 and Mean rank = 32.95).

The comparative analysis performed according to the existence of a diagnosis of chronic disease indicates that there are significant differences for the variables confirming the diagnosis of COVID-19 ($p < 0.001$) and the fear of infection with COVID-19 from university colleagues ($p = 0.037$). In this case, those suffering from chronic diseases obtained a higher score on the variable that refers to the fear of infection (Mean rank = 48.00). Students who do not suffer from chronic diseases obtained a higher score on the variable confirming the diagnosis of COVID-19 (Mean rank = 36.00).

Significant results were identified between variables considering confirmation of COVID-19. Thus, the scores obtained for the variable "How satisfied are you with your academic results during the restrictions related to the COVID 19 pandemic?" are higher in those who received a positive diagnosis for COVID - 19 ($p = 0.036$, Mean rank = 63.50). Students who did not receive a positive diagnosis for

COVID-19 scored higher on the variable of depressive disorder that occurred during the pandemic ($p = 0.042$, Mean rank = 35.82).

Correlation analysis

Our results indicate a statistically significant relationship ($p < 0.001$, $r = 0.514$) between the chronic disease status of students and the confirmation of the diagnosis of COVID-19, in the sense that those suffering from a chronic disease were more prone to become infected.

The level of satisfaction regarding the mental health of the students during the pandemic correlates negatively with the depressive ($p = 0.001$, $r = -0.390$) and anxiety disorders ($p = 0.009$, $r = -0.312$), and the level of satisfaction regarding the physical health correlates negatively with sleep disorders ($p = 0.023$, $r = -0.255$) and boredom level ($p = 0.041$, $r = -0.247$). In this situation, an increased level of depression and anxiety decreases the level of satisfaction with mental health, while a high level of boredom and the occurrence of sleep disorders lead to a decrease in the level of satisfaction with physical health.

Statistically significant relationships were identified between drug use and fear of COVID-19 infection during participation in practical activities at the faculty ($p = 0.016$, $r = -0.290$), fear of COVID-19 infection from patients encountered during internships ($p = 0.012$, $r = -0.299$), fear of COVID-19 infection from colleagues encountered during practical stages and lectures ($p = 0.006$, $r = -0.325$). In this case, fear of infection with COVID-19 decreased in students who used drugs. Also, alcohol consumption is correlated with sleeping disorders ($p = 0.038$, $r = -0.250$).

The variable "Courses are more interesting online" correlates positively with the level of satisfaction of students regarding the relationship with colleagues during the pandemic ($p < 0.001$, $r = 0.476$) in the sense that the more pleasant the relationships between colleagues are, the more interesting online courses become.

At the same time, the use of an electronic platform for teaching activities correlated positively with the idea that online activity is more interactive than that within the learning institution ($p = 0.001$, $r = 0.377$). The fact that online courses are more interesting correlated with an increased level of focus on new information in this environment, as opposed to laboratory attendance ($p <0.001$, $r = 0.692$) in the sense that an interesting online course leads to increased concentration.

The efficiency of online teaching positively correlated with the good functioning of the internet connection ($p = 0.038$, $r = 0.250$), in the sense that the better the internet connection, the more efficient the online teaching is. Also, the efficiency of online teaching ($p = 0.001$, $r = 0.389$) and the good training of teachers to use the online platform and the audio-video means necessary for the activity (p, 0.001, $r = 0.441$) correlated with the full follow-up of the online course / laboratory.

DISCUSSION

The duration of the social isolation and the predominant use of online education is still unpredictable. This research was conducted during the first semester of the second academic year in which the lockdown was imposed.

Even if 1/3 of students were suspected of being infected with COVID 19, only 2.9% of the total respondents were confirmed to have been positive. This aspect is

important because senior students have already achieved the standards of self-protection, they have great experience in working in clinics and they know how to manage their contact with patients, maintaining the required protocols regarding their hygiene and health. This result is encouraging because some studies already presented in specialty literature showed that medical dentistry presented high rates of infection among students due to poor knowledge and insufficient infection prevention. Ghai states that the current dental curriculum does not cover infection control adequately (especially from airborne pathogens). The author states that infection control education needs to be included in the dental curriculum worldwide. Academic teachers must provide adequate knowledge and attitudes related to infection control measures and teach students how to protect themselves and their patients, too (6).

The self-isolation was identified by a few studies published in the first six months of the pandemic period to be responsible for symptoms of depression, anxiety, and high levels of fear of infection. For students, concern about the delay in completing their graduation is an additional trigger for stress and depression, especially for those enrolled in their final year. This context can cause anxiety, poor sleep or short sleep durations, predisposing people to depression and post-traumatic stress disorders PTSD), as Tang *et al.* (7) identified in Chinese students (9.0% for depression and 2% for PTSD). In the present research, 10% of investigated students had frequent sleep and appetite disorders and 1/3 of them felt bored during the last months. The results are congruent with those presented by Emami (8) who pointed out that new perceptions must be incorporated into the new academic scenario, including students' wellbeing, feelings of loneliness, and familiar losses.

Poor physical and mental health negatively impact learning and academic achievement. From all respondents, we identified that only 18% of students were totally satisfied with their academic achievement during pandemic period. A great number of students felt bored, and some of them felt anxious and depressed. Tang *et al*. (7) showed that the psychological consequences of COVID-19 could be serious and psychological interventions are needed to reduce fear for the home-quarantined university students.

Quinn *et al.* (5) gathered data from dental faculties in Europe and identified that all dental schools reported access restrictions to academic buildings and provided online education. On the other hand, the academic risk for all students from clinical years is greater than those from preclinical years. Face-to-face practical classes containing interaction with real patients and simulation models is no longer a valid option for the acquisition of mental skills and manual skills for senior students. In Unites States, Deery (9) identified gaps in dental schools' preparedness for pandemics and this opinion is common for many countries in Europe, too. Also, theoretical, and practical examinations were redesigned but despite the reorganization and resilience of the academic staff, problems arise for both teachers and students: disruption of dental students' activity, interrupted access for students to dental faculty clinics; financial loss etc. (10)

Online tools are replacing face-to-face interaction, but our study revealed that senior students prefer more school-based courses than online ones. In a recent study,

Chang *et al.* (11), interviewed academic teachers from different dental schools and showed that the COVID-19 pandemic affected dental education a lot. It is true that intelligent technology surely has a lot of benefits for the learning process of dental education (12), but this is not enough for seniors' dexterity and practical achievement. In many schools, dental practices have closed or have been significantly reduced, while students were stressed about their grades and professional abilities. In a focus group conducted by Hasan & Bao (13) it was shown that students were afraid of "e-Learning crack-up" and "fear of academic year loss". The study proved that fear of academic year loss is the key responsible factor for psychological distress during COVID-19.

Strengths and limitations of the study

This study is the first one focusing on Romanian dentistry students' personal and academic life during pandemic period. Due to its entirely practical formation, the dentistry specialization needs an interactive and instructive formation, with the present research identifying the fact that dentistry students are very aware of the importance of practical stages and the level of knowledge for their future career. The second strength of the study is reflected by the investigated population: senior students (compared to freshmen or sophomores) are more prone to objectively appreciate the changes in the way of teaching and practicing.

The first limitation of the study is related to the low number of students involved in the research, limiting a stronger analysis of data considering some variables like (gender differences, rural/urban, accommodation). Because of this limitation, results cannot be generalized.

CONCLUSIONS

There is a great impact of the COVID-19 pandemic on dental education. The traditional model of dental education should be innovated to be suitable to different situations and must use diverse and intelligent technologies.

Academic staff should provide both educational and psychological support for senior students to adequately adjust to the new way of learning/teaching/being evaluated and to help them be professionally well-prepared for practicing during the next time frame of continuing pandemic.

NEWS

IMPACT OF COVID-19 INFECTION AMONG LIVER TRANSPLANT RECIPIENTS

Transplant recipients compared to general population are deemed at a particularly high risk for developing COVID-19 severe infection due to their altered immunological status mainly caused by long term administration of immunosuppressants. Although data on COVID-19 infection among liver transplants are scarce and heterogenous and even though the results show a possible beneficial effect of immunosuppression regimen on COVID-19, the underlying mechanisms remain unclear and trends among transplant physicians are to reduce the immunosuppression dosage, especially of the antimetabolite drugs, carefully evaluating case by case in order to balance the risk of rejection which could potentially be more harmful than immunosuppression itself. (Parente A, Manzia Maria T, Angelico R, *et al.* COVID-19, liver transplant, and immunosuppression: Allies or foes? *Transpl Infect Dis* 2020; 00:e13417. https://doi.org/10.1111/tid.13417).

JOINT DISEASE AND ITS MEDICAL AND SOCIO-ECONOMIC IMPACT ON HEMOPHILIA CARE IN ROMANIA (Abstract): Hemophilia is a congenital, hereditary, rare bleeding disorder, which fortunately has nowadays an optimal therapeutical solution, namely a life-long replacement therapy (RT) with the missing coagulation factor VIII (hemophilia A) or IX (hemophilia B). Inappropriate treatment results in secondary morbidity, dominated by the chronic hem arthropathy, with high medical and socioeconomic burden. **Objectives**: As in our country, RT has been started only in 1997 and a real prophylactic replacement (PR) only in 2016/2017, we aimed at conducting a study of persons mainly with prophylactic RT and of those mainly with on-demand (OD) regimen for obtaining a comparative evaluation of the medical and socio-economic outcomes. **Material and methods:** This observational cross-sectional patient-reported outcome (PRO) survey included 122 patients with a severe form of the disease, willing to answer to a large questionnaire with 56 items focused on 4 domains: socio-demographic, medical, quality of health and life, and direct costs of care. **Results:** There have been assessed striking, statistically different results, concerning the markers which reveal clinical severity (annualized joint and non-joint bleeding rate, target joints, hem arthropathy), the need for chronic analgesic therapy and orthopedic interventions, frequency of deficiency, disability, handicap and social assistance in the group of persons with OD treatment *vs.* PR. The high costs related to surgical interventions and occurrence of inhibitors have been underlined, related to a secondary morbidity of hemophilia. **Conclusions:** The favorable effects of PR are evident also in our country; its high costs are counterbalanced by the deleterious health and quality of life results of OD treatment, and also by its high costs for the specific secondary morbidity, pleading in the favor of PR, in accordance with the principles of care in Europe. **Keywords:** PRO-SURVEY, HEMOPHILIA, HAEMARTHROPATHY, QUALITY OF LIFE, COSTS OF CARE.

Hemophilia is a congenital, monogenic, hereditary, X-linked disease belonging to the group of rare, often "orphan" disorders. It is an incurable disease, requiring a life-long replacement therapy with the deficient coagulation factor: VIII (hemophilia A - HA) or IX (hemophilia B - HB) (1, 2, 3). It is clinically defined by recurrent bleeding events, the most vulnerable site being the joints. Early introduced, adequate replacement therapy (RT) can prevent its crippling evolution, otherwise resulting in the most important disease-related secondary morbidity, the chronic hemarthropathy (3, 4).

In Romania, the RT with coagulation factors concentrate (CFC) has been introduced in 1997, the regular prophylactic replacement (RPR) with the missing coagulation factors, being really introduced only in 2016/2017 (5). As we accept that "we can't manage, what we don't measure" (Lord Kelvin, 1883), we decided to conduct a patient-reported outcome (PRO), model of survey for obtaining an insight into the real-life of persons with hemophilia (PwH) in our country, looking for a most reasonable, effective and affordable solution according to the European principle of hemophilia care (6).

STUDY DESIGN

It is a retrospective cross sectional observational study of persons with hemophilia (PwH) and its related von Willebrand disease (vWD), diagnosed and treated in 11 neighbor counties from the Western part of Romania; with an acceptance rate of 62.4%, there were 122 patients included in the study. We used a PRO model survey, based on a specific questionnaire administered by e-mail, relative to a time interval of 12 months (1st January - 31 December 2019). All participants expressed their informed consent, and the Institutional Ethics Committee approved its performance.

OBJECTIVES

Our study was focused on 2 subgroups of patients, the assignment being based on their therapy regimen; subgroup 1, mainly with prophylactic replacement (PR) and subgroup 2, with mainly on demand (OD) therapy, having 4 objectives:

- to assess the frequency and severity of joint disease in our PwH, comparatively in the two subgroups of patients,
- to evaluate the impact of joint disease on the health and Quality of life (QoL),
- to estimate the costs related to the joint disease and
- to compare their dimension, depending on the treatment regimen PR or OD replacement.

MATERIAL AND METHODS

The study population consisted of 122 patients with severe (115) and moderate with severe phenotype (7) of hemophilia A (92), hemophilia B (16), and severe form of vWD (14). The cohort was divided into 2 subgroups: subgroup 1, consisting of 39 patients born after 1997 with a history of RT since their early childhood and subgroup 2 of 83 patients born before 1997, the year when RT was introduced in our country, lacking this treatment for a period of time (tab. I).

The study was based on a comprehensive questionnaire, administered to the patients, consisting of 56 items, for recording appropriate information on 4 domains: socio-demographic - 9, medical - 31, quality of health and life - 10 and the direct costs of treatment - 6.

TABLE I

Characteristics of the patients in subgroups 1 and 2

Variables	Subgroup 1 (39)	Subgroup 2 (83)	p-value
Age (years) (X ± SD)	11.3 ± 6.51	39.7 ± 10.79	<0.001
BW (kg) (X ± SD)	38.87 ± 27.02	79.91 ± 17.98	<0.001
HA -moderate	1(2.56%)	4(4.82%)	0.1
-severe	25(64.10%)	62(74.70%)	<0.001
HB -moderate	1(2.56%)	1(1.21%)	-
-severe	7(17.95%)	7(8.43%)	-
vWD -severe	5(12.82%)	9(10.84%)	<0.01
Therapeutic regimen			
-OD	3 (7.69%)	33 (39.76%)	<0.001
-STP	6 (15.38%)	43 (51.81%)	<0.001
-RPR	30 (76.92%)	7 (8.43%)	<0.001
Age at start of replacement (years)	2.22 ± 1.88	18 ± 10.69	<0.01

BW-body weight, HA-hemophilia A, HB-hemophilia B, vWD-von Willebrand disease, RPR-regular prophylactic replacement, OD-on-demand, STP-short term prophylaxis

For the economic evaluation of direct medical costs, the following parameters were considered: specific medicines - coagulation factor concentrates (CFC) and bypassing agents (BPA), biological and imagistic assessments for diagnosis and monitoring, hospital admission, and ambulatory bleed-related activity. All data regarding the real costs were sourced from the administrative departments of the treating clinics and from publicly available data, expressing them in national currency exchanged in EUR at the present rate. For the evaluation of health quality much attention was dedicated to the impact of treatment on the main hemophilia - related secondary morbidity, the chronic hemarthropathy, an important driver of budget consumption; the surrogate markers for its severity like annualized bleeding rate (ABR), annualized joint bleeding rate (AJBR), target joints, need for invasive orthopedic intervention, life-threatening bleeds were used. In connection with quality of health, QoL was evaluated using generic instruments, largely used in hemophilia assessments: EQ-5D and VAS; they aimed at receiving an insight into 5 domains: mobility, self-care, usual activities, pain/discomfort and anxiety/depression. Additionally, the International Classification of Functioning (ICF) of WHO for the estimation of function and participation of patients, was used, in connection with some social consequences.

Statistical analysis was performed using *Microsoft Office Excel* 2013 and *SPSS 14.0* for Windows Evaluation Version, calculating the average and standard deviation with significance at $p<0.05$ and correlation coefficient, significant when $r > 0.4$.

RESULTS

This PRO survey brings to our attention the great burden for hemophilia of the secondary age-independent chronic hemarthropathy present in 69.88% *vs.* 20.51% of patients from subgroup 2 *vs.* 1, respectively, being in 69.88 % *vs.* 12.82% with multijoint involvement (tab. II).

ABR and AJBR were significantly higher in patients of subgroup 2, their values being 19.42-ABR and 19.75-AJBR, in

comparison with subgroup 1 ($p<0.001$). Target joint, meaning ≥4 bleeds in the same joint occurring in a period of 6 months, another surrogate marker of severity, was concordant with the AJBR, 55.42% *vs.* 17.95% and multi-articular in 40.96% *vs.* 7.69% in the subgroup 2 *vs.* subgroup 1, respectively.

TABLE II

Joint disease and its impact on health and quality of life

Variables	Subgroup 1 (39)	Subgroup 2 (83)	p value
ABR	4.76±11.20	19.75±17.36	<0.001
AJBR	2.41±7.21	19.42±16.78	<0.001
Patients with chronic hemarthropathy	8(20.51%)	58(69.88%)	<0.001
Polyarticular chronic hemarthropathy	5 (12.82%)	58 (69.88%)	<0.001
Patients with target joints	7(17.95%)	46(55.42%)	<0.001
Polyarticular target joints	3 (7.69%)	34(40.96%)	<0.001
Invasive intervention			
-orthopedic	0	9 (10.84%)	0.001
-non-orthopedic surgery	1 (2.56%)	4 (4.81%)	<0.01
Acute pain	5 (12.82%)	29 (34.94%)	<0.001
Chronic pain	13 (33.33%)	56 (67.47%)	<0.001
Use of analgesics	5(12.82 %)	35(42.17 %)	<0.001
Polypharmacy	0	10 (12.05%)	<0.001
AJBR-Age correlation	r=0.32 p=0.045	r=-0.03 p=0.85	-
AJBR-Target joints correlation	r=0.86 p<0.001	r=-0.04 p=0.80	-
AJBR-Chronic arthropathy correlation	r=0.77 p <0.001	r= 0.40 p=0.005	-

ABR-annualized bleeding rate, AJBR-annualized joint bleeding rate

In patients of subgroup 1 the frequency of hemarthrosis and AJBR were dependent on the age and it is evident the correlation between AJBR, target joints, and the development of the chronic arthropathy; in subgroup 2 the AJBR is not anymore related to target joints and age, remaining in correlation only with hemarthropathy (tab. II).

This depressing history of frequent joint bleedings was naturally accompanied by suffering, chronic pain affecting 67.4% of PwH of subgroup 2 *vs.* 33.3% in subgroup 1, requiring daily analgesic drugs in 42.17% and even polypharmacy (> 5 different drugs at the same time) in 12.05% in the same group of patients, respectively.

It needs to be underscored that joint disease was present in both subgroups of patients, as they all had a period in their life not covered by RT, but the worse outcome of PwH of subgroup 2 is connected with the late start of RT at the age of 18.10±10.0 *vs.* 2.22±1.83 years in subgroup 1 (tab. I).

Beside the locomotor deficiency, disability, and handicap, the pain was the most decisive reason for invasive orthopedic interventions. Out of 14 invasive interventions performed in the analyzed year (2019), 9 (75%) were orthopedic surgeries, mostly arthroplasty (hip - 3 and knee - 4), exclusively performed in patients from subgroup 2.

The impact on health and quality of life was decisive (tab. III). It was impressive in subgroup 2, with an EQ-VAS of 0.63 ± 0.14 *vs.* 0.84 ± 0.19 in subgroup 1, with the association of disability and handicap in 56.98%, with social assistance or sick retirement in

62.82% of the persons of the subgroup 2. Frequent absences from work and loss of productivity for not being active at work are also to be mentioned.

TABLE III

The impact on QoL and social condition

	Subgroup 1 (39)	Subgroup 2 (83)
Quality of life(EQ -VAS)	0.84 ± 0.19	0.63±0.14
ICF classification		
-deficiency	8 (20.5%)	34 (40.96%)
-disability	-	30 (36.14%)
-handicap	-	17 (20.84 %
Sick retirement	-	10 (12,82%)
Social assistance	2 (5.13%)	39 (50%)
Absence from school/ work		
-number of persons	5 (12.82%)	14 (16.87%)
-days/person/year	1.92	7.53

AJBR-annualized joint bleeding rate, EQ-VAS-EuroQol-visual analogue scale, ICF- International Classification of Functioning

All these outcomes were accompanied by the evident high medical and psychosocial burden for our PwH, who missed for years in their young age RT and are still receiving OD RT. From the standpoint of the costs, looking at the expenses of surgical interventions and the other direct costs, we realize the high values, which could have been avoided with an adequate RT (tab. IV). It is to underline that out of 14 patients who underwent invasive intervention in 2019 (the year of our study), 13 belong to subgroup 2, 9 of them having chronic hemarthropathy related orthopedic surgery. The distribution of the annual direct costs/patient, consisting of the expenses for medication, diagnosis and monitoring assays, medical devices, hospital stay, in those 9 patients who needed major orthopedic invasive interventions are presented in the fourth table.

TABLE IV

Distribution of average costs of orthopedic invasive interventions /patient/year (EUR)

PwH	Cost of investigations / monitoring	Cost of CFC	Cost of medical devices	Total cost/patient/ intervention
Average ±SD	568.04± 116.93	44,399.71±17,592.88	1,273.63±158.70	46,241.38

(PwH-persons with hemophilia, CFC-coagulation factor concentrates)

DISCUSSION

The recurrent bleedings have dominated over centuries the clinical image of hemophilia, (1, 4). The introduction of RT with CFC and BPA, since more than five decades ago, has succeeded to control the bleeding events and save lives, but without significantly changing the handicapping outcome of the bleeding-associated joint disease. Only the introduction of PR has brought a revolutionary change in hemophilia care, preventing and /or slowing down the progressive joint damage.

Today, in an era with a large landscape

of CFC, it has been accepted that prophylaxis is the standard of care (7, 8). This decision is based on controlled randomized prospective clinical trials which have proved that ABR and AJBR, as well as joint scores, are significantly improved by this approach.

The ESPRIT study conducted on children reported an ABR of 1.32 *vs.* 5.76 and an AJRB of 0.6 *vs.* 2.88 in the group with PR and that with OD therapy, respectively (9). Another clinical randomized study conducted on children under the age of 30 months, with subgroups assigned to receive prophylaxis (25 IU/kg each other day-EOD) or enhanced episodic OD therapy indicated an ABR of 3.27±6.24 *vs.* 17.69±9.25 and an AJBR of 0.63±1.35 *vs.* 4.89±3.57, undoubtedly better in the first group of patients with PR (10). Another study dedicated to children, comparing two types of prophylaxis regimens (EOD and pharmacokinetic–PK driven) with OD replacement, revealed that the ABR was 43.9±21.9 in the OD group in comparison with 1.6±1.2 with the EOD group and 1.9±11 in the group with PK-driven prophylaxis, respectively, both being significantly lower (11). The same good results are demonstrated for hemophilia B. In a multicenter randomized open-label study the results of RP *vs.* OD were significantly better ($p<0.001$) in both two subgroups of patients with hemophilia B, irrespective of the treatment regimen, 100 IU/kg once/ week or 50 IU x 2/kg /week (11). A comparable situation was found in adolescents and young adults in another randomized study: the AJBR value of 0.63±1.35 *vs.* 4.89±3.57 and the ABR of 3.27±6.24 *vs.* 7.69±9.25 in the group of prophylaxis and that of OD RT, respectively, impacting in a favorable manner also the joint health and the quality-of-life parameters (12).

The high effectiveness of RPR is doubtless, even with slight differences in the lower dosage regimen *vs.* OD. The comparative study between the Dutch and Swedish regimen, with the weekly dosage in IU/kg of 46 (34-55) *vs.* 88 (61-113) respectively, assessed a better AJBR, joint function, and EQ-5D in the higher dosage regimen (13). At the same time, it is worth to be mentioned that even in the situation of very low dosage (10-30 IU/kg/week) prophylaxis (ReCare trial) the ABR rates were in comparison to the baseline significantly lower, the best being the results of primary prophylaxis (14).

There are other studies, showing significantly improved results also even in the case of late initiation of tertiary prophylaxis. In the POTTER study undertaken in adults, stratified into two age groups (12-25 and 25-55 years), the introduction of PR revealed a dropping of AJBR from 16.8 to1.97 and from 16.71 to 2.46 in the two age groups, respectively (15). The delay of starting RP as primary prophylaxis is confirming the statement that "one (joint) bleed is too much", as it can initiate the vicious circle of synovium and endochondral damages. A comparative study performed in 4 countries (Sweden, United Kingdom, Ireland, and France) is highlighting the fact that early joint bleeding can impact the long-term outcome, leading to inferior results. Sweden, the first country which started early RP, has significantly better values for ABR, target joints, EQ-5D, missed days from work than other countries (16). Similar results come from the Canadian observational study performed on two age groups of adults (>18 years of age) PwH, younger and older than 40 years of age, one group which started

PR and the other remaining on OD therapy. In both age groups, the reduction of ABR was significantly better ($p<0.001$) than in the group of OD treated persons, but in the groups of OD treatment, there were no significant differences ($p = 0.86$) between PR and OD (17, 18). Striking differences are assessed also in the northern countries (Norway, Sweden), patients with OD in comparison with PR having a need for invasive intervention in 28.75 *vs.* 4.91, with a proportion of sick leave/early retirement of 36% *vs.*13%, respectively (19). Switching from PR to OD in late teens has also deleterious effects (20). All these studies (15-20) are motivating us to hope for a better future in our country for those who didn't experienced PR and to support the decision of maintaining it for PwH who benefited from it, in accordance with our national program, until the age of 18 years.

We believe that the threshold of reimbursement for PR in young adults or even older in our country would be affordable (21, 22). The limit of our study is connected to the short duration of our survey. The condition is to perform a cost-utility and cost-effectivity study on large horizon, including comprehensively all the direct and indirect costs; incremental cost-effectiveness ratio (ICER) calculated in these circumstances would be certainly in the range of acceptance for our country, like in other European countries (23-25).

CONCLUSIONS

The favorable effects of our short history of PR with CFC are evident in our country, as there are the deleterious effects in its absence, supporting the idea of prophylaxis in severe hemophilia in accordance with the principle of hemophilia care in Europe.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

THE WALKING THRU THE PAST AND THE PRESENT OF HIRSCHSPRUNG DISEASE (Abstract): Hirschsprung's disease or congenital megacolon is one of the differential diagnoses of chronic constipation mostly in infancy and may indeed represent a challenge for pediatricians, pediatric surgeons, and pediatric pathologists. The diagnosis relies clearly on the identification of the absence of ganglion cells at the plexuses (submucous and myentericus) of the bowel wall. Hirschsprung's disease) is usually located at the terminal (distal) rectum with potential pre-terminal or proximal extension to the less distal large bowel (sigmoid colon). Astonishingly, there is some evidence that Hindu surgeons of prehistoric India may have been exposed and had considerable knowledge about Hirschsprung's disease), but this disease is notoriously and eponymously named to Dr. Harald Hirschsprung (1830-1916), who brilliantly presented two infants with fatal constipation at the Berlin conference of the German Society of Pediatrics more than one century ago. Hirschsprung's disease has been originally called "Die Hirschsprungsche Krankheit"). More than 100 years following his meticulous and broad description, Hirschsprung's disease is still a puzzling disease for both diagnosis and treatment. Hirschsprung's disease remains a critical area of clinical pediatrics and pediatric surgery and an intense area of investigation for both molecular and developmental biologists. **Keywords:** DR. HARALD HIRSCHSPRUNG, HIRSCHSPRUNG'S DISEASE, CONGENITAL MEGACOLON, HISTORY.

Medical history is fascinating and, since its beginning, it was meant to enlighten scientific issues, booster the medical profession, and celebrate the traditions or tales of particular places. Harald Hirschsprung, who presented two infants with fatal constipation at the German Society of Pediatrics more than one century ago. Is known in medicine for his eponym of intestinal aganglionosis. Events running before and after Dr. Hirschsprung's discovery may drive interest in medical students and doctors to review the diagnostic procedures of this intriguing disease and recognize the enormous input given from microscopy and pathology to this diagnosis.

Hirschsprung disease, first described in detail by Harald Hirschsprung in 1886, is a congenital disorder characterized by the absence of ganglion cells in the myenteric and submucosal plexuses of the gastrointestinal tract, leading to functional bowel

obstruction. Despite its long history, the scientific community is still unraveling the complexities and intricacies that define this disease. As a condition that impacts thousands of newborns globally each year, Hirschsprung disease poses unique clinical challenges that necessitate a multidisciplinary approach involving pediatricians, gastroenterologists, surgeons, and geneticists, among others.

This article aims to walk through the historical landmarks that have shaped our understanding and management of Hirschsprung disease, from its initial identification to the modern era of molecular genetics and targeted therapies. It will explore the diagnostic and therapeutic advancements that have transformed patient outcomes and shed light on the current research frontiers that hold the promise of even better management strategies. Additionally, the article will scrutinize the existing gaps in our knowledge and identify areas where further research is crucial for more effective treatment and improved quality of life for affected individuals.

By bridging the past and present, this comprehensive review provides not only a historical perspective but also an up-to-date overview of Hirschsprung disease, thereby serving as a valuable resource for clinicians, researchers, and medical students alike.

MATERIALS AND METHODS

A comprehensive search strategy was devised to include articles from the earliest available records to September 2023. Keywords and phrases used in the search included but were not limited to: “Hirschsprung Disease”, “Congenital Aganglionic Megacolon”, “Colonic Aganglionosis”, “Ganglion Cells”, “Treatment”, “Diagnosis”, “Genetics”, and “Pathophysiology”.

The databases utilized for the literature search in this review include PubMed, Web of Science, and ScienceDirect. These databases were chosen for their wide scope, accessibility, and credibility within the scientific community.

The studies were selected based on the following *inclusion criteria*: Original research articles, reviews, case studies, and clinical trials focused on Hirschsprung disease / Articles published in peer-reviewed journals / Studies that contributed to the historical understanding or current advancements in diagnosis, treatment, and management of the disease.

The *exclusion criteria included* were: Articles not available in English / Duplicate studies or those that did not contribute new information / Papers lacking methodological rigor, as assessed by the authors.

The data was then organized into themes pertaining to the historical milestones, diagnostic methods, treatment options, and future research avenues in Hirschsprung disease. This thematic organization facilitated the narrative synthesis of existing literature and helped identify gaps for future research.

By adhering to this methodological framework, this review aims to present a balanced and comprehensive overview of Hirschsprung disease, tracing its historical roots and elucidating its present landscape to identify the most promising paths for future research and clinical practice.

BRIEF HISTORY

Young Harald Hirschsprung was born in 1830. He decided not to join the family’s tobacco company to study medicine. Medical studies would become an indirect reason for Hirschsprung’s name to gain immortality. For more than 100 years congen-

ital intestinal aganglionosis, whose macroscopic pathology he described in such detail, has been known worldwide as Hirschsprung's disease (1).

Harald Hirschsprung (1830-1916) was the founder of Danish pediatrics, and during his work as professor and chief physician of the Queen Louise Children's Hospital, he made the hospital a home of Danish pediatric research. Dr. Hirschsprung positioned Danish pediatrics internationally, had close relationships with foreign scientific societies and used to attend pediatrics congresses in Germany and Austria every year (fig. 1).

Fig. 1. Harald Hirschsprung (Source: https://ugeskriftet.dk/videnskab/harald-hirschsprung-og-den-kongenitte-aganglionose)

In 1886, Hirschsprung held the lecture "Stuhlträgheit Neugeborener in Folge von Dilatation und Hypertrophie des Colons" in Berlin at the annual congress of the German Society for Children's Diseases. He was referring to two cases of the disease that Hirschsprung had observed in 1880 and 1885 respectively at the Dronning Louises children's hospital. In the introduction to the lecture, he said: "I take the liberty to present to this erudite assembly two presentations of an unusual nature and at the same time briefly explain the associated medical histories (1)." The first presentation was described as follows: "As you can see, it is a large intestine, but of such a size that it will no doubt surprise you to learn that the intestine came from a child who died only at 11 months of age." In the presentation it was also said that the colon, in addition to being dilated, was also significantly thickened. The dilatation extended into the rectum which appeared normal. The child, who had been constipated since birth, had worsened at eight months of age when Hirschsprung first saw it. Constipation required frequent enemas, the abdomen became strongly prominent, and the child lost weight rapidly. Eleven months later it died. The second case described by Hirschsprung was similar (2).

In the following years Hirschsprung saw several similar cases of the disease and wrote about this condition in one of his works: "It is strange that a form of disease like this which nevertheless produces such prominent symptoms and is of such great importance for the patient is left completely unmentioned in the pediatric literature. However, given my experience, I cannot believe that the condition must really be that rare. But maybe it will happen so often that attention needs to be paid just to make the cases more frequent". This assumption turned out to be correct. In the following years, an increasing number of reports of these cases of the disease, which were already internationally referred to as Hirschsprung's disease, were mentioned.

Hirschsprung was convinced that the

disease was congenital, however, it was not until the late 1940s that basic aganglionosis in the rectosigmoid was detected and thus the basis for rational surgical treatment was simultaneously created (3).

Doctor Harald Hirschsprung

Dr. Hirschsprung, who graduated with a degree in medicine in 1855, showed since his first steps into medical career a strong interest in pediatrics, becoming astoundingly the chief physician of the only children's hospital in Copenhagen just fifteen years later. The appointment as professor of pediatrics came in 1877 and Dr. Hirschsprung became director of a larger children's hospital in Copenhagen from 1979 until 1904, when he retired. The new children's hospital was magnificently named after Denmark's Queen Louise (The Queen Louise Hospital for Children). Dr. Hirschsprung was fond of anatomical variations, peculiar aspects of medicine, and intriguing diseases. He was a brilliant teacher with loyal and faithful students. Between 1880 and 1885, Hirschsprung came across two infants with similar clinical presentation. The first child had bowel problems that persisted soon after birth with absence of spontaneous bowel movements. Daily enemas and laxatives were necessary. The second case had similar bowel distensions with terminal bouts of diarrhea variably alternating with impossibility to evacuate. Notwithstanding the scarcity of information continuous therapy was applied, but, unfortunately, both children eventually died and a post-mortem examination was performed. At the autopsy, the rectum was narrowed, but there were striking dilation of the bowel loops with some ulceration of the mucosa associated with thickening of the bowel wall. In his publication, Dr. Hirschsprung summarized his findings and drew attention to the typical clinical presentation of both cases. In an opinion, which is worldwide shared, his meticulous and comprehensive description is not the first one to indicate details of this disease, but he provided a complete and excellent account of this entity in consideration of his clinical experience and practice in pediatrics. The name "Hirschsprung's disease" came into widespread use shortly before the end of the 20th century and, in 1916, Hirschsprung himself added an additional 10 more cases before his death (2).

Pre-Hirschsprung Era

The examination of the scientific literature seems indicate that approximately 20 similar cases have been recorded between 1825 and 1888. However, there is evidence that Hindu surgeons of prehistoric India had considerable knowledge about Hirschsprung's disease. Sushruta's description of a disease called Baddha Gudodaram is extraordinarily analogous to that of Hirschsprung's disease. Semantically, it seems indicate "abdominal distension due to blocked rectum".

According to Sushruta, Baddha Gudodaram is a type of disease caused by (functional) blockage of the ano-rectal canal. The affected child or, even, young adult may show rectum and distal colon stuffed with gas, "stones" (fecaliths), "hair" (undigested fibers), and, obviously, feces. In the child, there is an abdominal distension, which is characteristically seen between the heart and the umbilicus. Scanty stools are evacuated with greatest difficulty, and, eventually, it was reported that the patient might vomit feculent fluid. However, the pre-Hirschsprung era is not complete, if additional reports are not also mentioned.

The Sushruta Samhita is an ancient volume of Ayurvedic surgery compiled by Sushruta (circa 1200-600 BC). Passages of interest were identified by browsing through the authentic English translation of the old compendium. The accuracy of the translation was verified by comparing it with the original Sanskrit verses with the help of a Sanskrit scholar. A condition called Baddha Gudodaram, described in the Samhita, closely resembles Hirschsprung's disease. There are indications that the ancient Indians even deciphered the etiology as defective vayu alias vata (2).

Although the disease was considered incurable, a palliative operation was discussed.

Descriptive details of the operation match those of sigmoid colostomy. Evidence from the Sushruta Samhita indicates that Hindu surgeons in prehistoric India probably had considerable knowledge of Hirschsprung's disease. Further research corroborating other sources of evidence is needed to confirm this claim (4).

Indeed, Fredericus Ruysch, a Dutch anatomist in Amsterdam (Netherland) in 1691 described a 5-year-old girl with abdominal pain. It seems that the usual treatment to relieve pain was permanently ineffi-cacious and the child continued to pass flatulence. No evacuation was practically possible and the child ultimately died (fig. 2).

Fig. 2. A historical overview of the discovery of Hirschsprung's disease (Source: http://old.semmelweis.hu/wp-content/phd/phd_live/vedes/export/ baradcsillamaria.d.pdf)

Domenico Battini, an Italian physician of the 19th century described a child that he followed up for 10 years with severe constipation. The child died and the autopsy demonstrated severe dilatation of the colon. The published Italian contribution showed

not only a very careful clinical evolution of the child, but also provided a detailed autopsy with examination of the abdominal viscera. Particular mention to the morphological alterations occurred in the large bowel were present in the original Italian publication. Through the examination of the reports, Fiori concludes that Dr. Battini, nearly one century before Hirschsprung, may have originally achieved its target in reporting an archetypal case of megacolon of congenital type. Distinctively, a number of characteristic features, including familiarity and the peculiar selective involvement of "neural layers" of the bowel, that later became characteristic of Hirschsprung's disease, were remarkably well postulated by Dr. Domenico Battini. To increase the controversy between Denmark and Italy as well as other countries, there may be a few more reports that need to be listed (5).

In 1836, Ebers reported a 17-year-old boy with a history of constipation since birth or, perhaps, as toddler, while Jacobi had also described two neonates with intestinal obstruction in 1869. Fragmentary reports of children who died of severe constipation appeared also in the literature in the pre-Hirschsprung era. In fact, Gee reported the autopsy findings of a 4-year-old child with a "spasm" of the sigmoid colon without involving of the rectum in 1884, while Bristowe described the outcome of an 8-year-old girl who died of mechanic ileus after longstanding severe constipation of the bowel (6).

Dr. Hirschsprung died on April 11, 1916, but his supreme legacy to clinical pediatrics, pediatric surgery, and pediatric pathology is unmatched with contributions that go further than severe constipation in children or the disease harboring his name ("Hirschsprungsche Krankheit") (fig. 3).

Fig. 3. A typical case handled by Hirschsprung in his hospital (Source: https://revista.svhm.org.ve/ediciones/2008/1-2/art-3/)

The Danish pediatrician observed and described in detail several diseases, including pyloric stenosis and intussusception. Dr. Hirschsprung indicated guidelines for management of a broad spectrum of pediatric diseases, including contributions in the area of teratology and clinical dysmorphology. These contributions are now part of the didactic activity and scientific investigation of innumerable professors and researchers of Pediatrics, Pediatric Surgery, and Pediatric Pathology. He participated actively to the building of the children's hospital and his dedication to children constant. Queen Louise wanted the wall spaces above doors to harbor biblical quotations for the edification of the sick children, but Dr. Hirschsprung considered more appro-

priate to give the children an environment that could bring some quietness. In consideration of the sensibility of the children, he firmly refused the holy quotations and suggested colorful and beautiful wall decorations of animals and flowers, which in the end were well accepted by the Danish crown to be inserted in the wall spaces above doors (7).

The Post-Hirschsprung Era

Recently, the interest has focused on the diagnosis of Hirschsprung's disease mainly because of the jeopardy of methods used to make the diagnosis and their accuracy. Being a genetic disease quite diverse, main topics on Hirschsprung's disease involve, indeed, the investigation of the best diagnostic marker for Hirschsprung's disease and changes that may take place during ganglion cell maturation. Hirschsprung's disease is now known as the most common cause of neonatal lower intestinal obstruction occurring in 1:5000 live birth newborns. Hirschsprung's disease involves in about three quarters of cases male children, and its incidence is variable according to ethnics (8). The caudal migration of the primordial neural crest cells starts at the upper end of the gut following progressively the vagal fibers distally. A delay or arrest in this migration induces failure of the neural crest cells to reach the distal bowel with consequent congenital abnormal nerve innervation of the bowel. There is a caudocranial severity, which means from the internal anal sphincter extending proximally for a variable length of gut. Pathophysiological, there is a proximal intestine, which is dilated and progresses to an abrupt or, alternatively, gradual transition to a normal calibrated distal bowel. This distal intestinal segment shows typically a funnel like or cone shaped zone in between (the so-called "transition zone"). Moreover, there is a proximal muscle hypertrophy. This anatomic and prominent feature of the colon, located proximal to the aganglionic segment, represents undoubtedly an effort to overcome the partial obstruction. The bowel becomes distended with thickening of its wall, and the degree of dilatation and hypertrophy depends intricately upon both the time and degree of obstruction and obviously, indirectly, to the age of the patient. Clinical presentation settings include failure to pass meconium within the 24-hrs. of life considering that 98% of newborns pass meconium in less than 24-hrs. of age, neonatal intestinal obstruction syndrome (abdominal distension, refusal to feed, and vomiting of bilious type), and recurrent enterocolitis (mainly infants less than 3 months of life), toxic megacolon, spontaneous perforation, and chronic constipation with persistent failure to thrive. Toxic megacolon includes fever, abdominal distension, bile-stained vomiting, explosive diarrhea, dehydration, and shock. History includes failure to pass meconium, painless abdominal distension, and, obviously, constipation. Physical examinations of children with Hirschsprung's disease includes enlarged abdominal circumference with numerous fecal masses (9). Digital or post-evacuation examinations reveal hypertonic anal sphincter, typical empty rectum, and hard fecal mass. Radiology (plain abdominal X-ray both erect and supine as well as contrast enema) typically shows narrow distal segment, funnel-shaped dilatation characteristically localized at level of transition zone as well as marked dilatation of the proximal colon. Moreover, a poor emptying of barium throughout the colon in 24 hours delayed films is also found. A differential diagnosis of "psychogenic" stool is requested and, in this latter case,

the barium generally collects in the distal recto-sigmoid colon. Electro manometry shows absence of the recto-anal inhibitory reflex (RAIR) when the rectum is distended. RAIR is defined as the reflex of relaxation of the internal anal sphincter following rectal distension (balloon). RAIR (+) means normal, while lack of RAIR, RAIR (-), means Hirschsprung's disease. Bedside or outpatient procedures seem to give no complications (10). The test is unreliable if the gestational age plus post-natal age is less than 39 weeks and birth weight is less than 2.7 kg. However, if, at neonatal age, electro manometry is useless, it represents a good screening tool in infancy and childhood. Ultrasonography is important to rule out associated anomalies and a genetic counselling may be considered appropriate according to the familiarity and the phenotype of the patients affected with Hirschsprung's disease. Rectal biopsy is the definitive diagnostic test showing absence of ganglion cells, presence of nerve hypertrophy, and increased acetyl-cholinesterase activity. It may include either a suction mucosal biopsy (at different levels) or a full thickness biopsy. Suction, transmural, and jumbo biopsies are the usual biopsies taken in an infant with severe constipation. It is a general opinion that pediatricians play a major role in diagnosing Hirschsprung's disease and dysmorphic features remain important landmarks that need to be identified first by clinical pediatricians and, later discussed with clinical geneticists. Typically, Hirschsprung's disease is clinically identified as a solitary gastro-intestinal anomaly in a full term, otherwise healthy newborn or infant, but associated anomalies do occur in about 1/5 of cases, including uro-genital system (11%), cardio-vascular system (6%), gastro-intestinal system (6%), and other systemic congenital defects (8%). In as many as 1/10 of children with Hirschsprung's disease, the condition of prematurity has been reported. Trisomy 21 syndrome (Down syndrome) occurs in approximately 1/20 of children with Hirschsprung's disease. The work of the pathologists is impressive and their criteria for diagnosing Hirschsprung's disease are quite straightforward and easy to follow in classic cases. It is important to highlight that not all-severe constipation mean automatically Hirschsprung's disease. Both the lack of ganglion cells and the hypertrophy of nerve fibers are pathologic landmarks of Hirschsprung's disease (8).

The diagnosis and surgical treatments of Hirschsprung's disease have undergone various changes in the last few decades because of establishment of laparoscopic procedures. A nationwide retrospective study conducted in Japan he used the patient data were collected in 4 phases: Group 1, between 1978 and 1982; Group 2, between 1988 and 1992; Group 3, between 1998 and 2002; and Group 4, between 2008 and 2012. The results of the study were that primary operations without laparotomy, including TAEPT and laparoscopy-assisted operations, have become the first choice for the definitive surgical treatment of HD in Japan. The mortality rate has decreased over time. However, the mortality rate of small intestinal aganglionitis is still relatively high. The development of new treatment strategy for small intestinal aganglionitis is called for (11).

In the year 2022 a new surgical procedure successfully addresses a common lingering challenge - incontinence - faced by some families with young children who have undergone surgery for Hirschsprung disease. This first-of-its kind procedure was pioneered by surgeons in the Division of Colorectal and Pelvic Reconstruction at

Children's National Hospital, led by Division Chief Marc Levitt, M.D. The new pilot study shows long-term outcomes for seven patients between the ages of 2 and 18 who underwent the novel technical approach called sphincter reconstruction. Each of the seven were diagnosed with an anatomic or physical issue contributing to their incontinence. It was during a repair procedure for the first patient that Dr. Levitt and his team had the idea of a technique for sphincter reconstruction. After that, six more patients with similar anatomy were offered the procedure.

The study regarding transcriptional Profiling, Functional Analysis, and Organoid Modeling of Intestinal Mucosa in Hirschsprung Disease it had as a conclusion that despite normal ganglionic structure, the section of colon adjacent to the aganglionic region in Hirschsprung disease and patients has perturbed gene expression which resembles the aganglionic segment. Transcriptional and functional changes in colonic epithelium are persevered in the ganglionic colon used for pull-through surgery. This may explain persistence of enterocolitis despite surgical excision of aganglionic colon and subsequent endorectal pull-through performed with aganglionic colon during correction of Hirschsprung disease (12).

Current evidence suggests that transplantation of enteric nervous system stem cells, sourced from easily accessible postnatal gut, could be a viable alternative treatment for Hirschsprung disease and ultimately for a number of other congenital or acquired enteric nervous system disorders.

Hirschsprung disease (HSCR) is a congenital anomaly of the colon that results from failure of enteric nervous system formation, leading to a constricted dysfunctional segment of the colon with variable lengths, and necessitating surgical intervention. The underlying pathophysiology includes a defect in neural crest cells migration, proliferation and differentiation, which are partially explained by identified genetic and epigenetic alterations. Despite the high success rate of the curative surgeries, they are associated with significant adverse outcomes such as enterocolitis, fecal soiling, and chronic constipation. In addition, some patients suffer from extensive lethal variants of the disease, all of which justify the need for an alternative cure. During the last 5 years, there has been considerable progress in HSCR stem cell-based therapy research. However, many major issues remain unsolved. This review will provide concise background information on HSCR, outline the future approaches of stem cell-based HSCR therapy, review recent key publications, discuss technical and ethical challenges the field faces prior to clinical translation, and tackle such challenges by proposing solutions and evaluating existing approaches to progress further.

CONCLUSIONS AND FUTURE DIRECTIONS

Since the clinical presentations by Harald Hirschsprung in Berlin in 1886, the condition that bears his name has had a rich history. The seminal events that influenced progress in the understanding and management of this complex congenital disorder have been briefly covered in this historical review. More than 100 years ago, the condition was considered incurable and uniformly fatal over time (12, 13). Mortality rates continued to be high in the 1940s (70%) and remained high even in the 1970s (25%). By the 1990s, more than 90% of patients survived (14).

Currently, the survival in most ad-

vanced medical environments is greater than 95%, excluding cases with chromosomal disorders or advanced comorbidities. While mortality has improved, there remains much to be learned. Why some patients with HSCR do poorly following operative repair remains an enigma. Similarly, the proper management of many patients with variants of HSCR needs to be more clearly elucidated. Continuing studies of the ENS and the molecular genetics of these conditions may shed further light on these issues and provide a better understanding of the choice of management in the future for affected children. Recent studies have transplanted human enteric neural progenitors into the mouse colon and shown engraftment (15). Currently, researchers are working to develop novel stem cell therapies, whereby stem cells could be transplanted into the aganglionic segment of bowel to replace the missing ENS.

A SHORT HISTORY OF THE HISTOLOGICAL PROCESSING TECHNIQUES FOR TOOTH AND SUPPORTING HARD TISSUES (Abstract): **Background and aim**: Mini-implants play an important role in orthodontic treatment. However, the mechanism of bone remodeling associated with these orthodontic devices is not yet fully elucidated. The research focusing on the dynamics of biological changes at the implant site frequently involves experimental animal models. Our study aims to evaluate, by imaging methods, the success rate of implantation process of orthodontic mini-implants, using an original experimental model for the study of tissue biological responses present at the bone – mini-implant interface. **Materials and methods**: The study was conducted on adult male Sprague Dawley rats divided into 9 groups of 6 rats (G1 – G9) in which two mini-implants were surgically implanted in the right tibia. Two rats in each group also acted as controls by inserting a mini-implant in the left tibia without force. After implantation, traction forces were applied between the two mini-implants with closed NiTi helical orthodontic springs. Springs were extended at 2.2 cm, generating a force of 100 gf (G1, G4, G7); at 1.4 cm, the force generated was 75 gf (G2, G5, G8); at 1.2 cm, the force generated was 50 gf (G3, G6, G9). Animals were sacrificed at 7 days (G1, G2, G3), 21 days (G4, G5, G6), and 42 days (G7, G8, G9) from implantation. On the day of harvesting, each rat was examined radiologically by Spectral AMI HTX, Spectral Instruments. **Results**: The overall mini-implant success rate was 94.1%. In 5.9% of the subjects, either distal implant fracture with spring detensioning or distal implant detachment was observed. In control mini-implants, without spring, the overall success rate was 100%. **Conclusions:** Imaging exams are valuable tools for analyzing bone remodeling, density, and in vivo structure of bone tissue. Our study confirms the effectiveness of imaging examination in verifying the stability of the implantation stage, as a mandatory step in the subsequent evaluation of morphological changes in peri-implant bone tissue.

INTRODUCTION

Advances in orthodontic practice are directly related to basic and clinical research focused on oral tissue morphology and craniofacial biomechanics (1-3). The basic principle of orthodontic treatment consists in the application of directed orthodontic forces to the teeth, resulting in concomitant remodeling of periodontal ligament and alveolar bone. The review of the literature underwrites several aspects of tissue transformation in the presence of force application (4). Another line of orthodontic research concerns the relationship between bone resorption associated with orthodontic movement and systemic medication (5).

Mini-implants play an important role in orthodontic treatment. The use of mini-implants is based on the development of implantation techniques because of the optimization of dental procedures, imaging studies of the oro-dental region and implant characteristics (design, biocompatibility). Mini-implants are an increasingly used treatment option, mainly motivated by the significant potential to shorten treatment (6). Through their action, they provide skeletal anchorage and prevent unwanted tooth movement. A major advantage is that no healing period is required after implantation, allowing immediate loading (7).

Although their use is on an upward trend and the clinical benefits are evident, the mechanism of bone remodeling associated with these orthodontic devices is not yet fully elucidated (4). This is mainly due to the difficulty in assessing the dynamics of positive and negative biological changes at the implant site. Consequently, translating the analysis of changes in the anatomical structures involved from the clinical, macroscopic level to the cellular and molecular level is a challenge for orthodontic research (8). For this purpose, specialist groups in the field are constantly using in vitro models and systems.

However, there are also opinions advocating the use of experimental animal models, which are superior as a possibility to test the efficacy and safety of application procedures - although the difficulties of extrapolating results to humans must be considered (9). In experimental studies, to complete the overall picture of bone tissue dynamics at the implant site, advanced imaging techniques can provide important information about the bone remodeling and evolution of treatment process. Nevertheless, the bone response is individualized, depending on several specific factors. Therefore, the design of an experimental study gains, in the relationship between methodology complexity and results consistency, by including an imaging assessment step.

Within this general context of knowledge, our study aims to evaluate, by imaging methods, the success rate of implantation process of orthodontic mini-implants, using an original experimental model for the study of tissue biological responses present at the bone – mini-implant interface.

MATERIALS AND METHODS

The study was conducted on 28-week-old adult male Sprague Dawley rats weighing between 340 g and 450 g, provided by the National Institute for Medical and Military Research and Development “Cantacuzino” (Bucharest, Romania). The ethical aspects of the research were strictly respected in accordance with the European Directive 2010/63/EU on the Protection of Animals used for Scientific Purposes, the European Convention for the Protection of Vertebrate Animals used for Experimental

and Scientific Purposes (Council of Europe No. 123, Strasbourg, 1985), and the guidelines established by the National Animal Welfare Authority (approval no. 64/12.09.2023). The study protocol was approved by the University's Research Ethics Committee (approval no. 59/ 23.03.2021).

The experiment was conducted over a period of 6 weeks. The experimental animals were divided into 9 groups of 6 rats (G1 – G9) in which two mini-implants were surgically implanted in the right tibia. Two rats in each group also acted as controls by inserting a mini-implant in the left tibia without force.

The type of mini-implant used was Dual Top Anchor System screws, diameter 1.3 mm, and length 5 mm, made of titanium alloy. After implantation, traction forces were applied between the two mini-implants with closed NiTi helical orthodontic springs, size: 0.008 x 6 mm, this type of springs generating continuous forces.

The forces were determined using the Sauter Digital Force Gauge FH 10, and the resulting distances were 1.2 cm, 1.4 cm, 2.2 cm. Thus, the spring extended to a distance of 1.2 cm generated a force of 50 gf on the mini-implant; at a distance of 1.4 cm, the force generated was 75 gf; at a distance of 2.2 cm, the force generated was 100 gf. Groups G1, G4, G7 were loaded with 100 gf, groups G2, G5, G8 with 75 gf, and groups G3, G6, G9 with 50 gf.

The animals were sacrificed as follows: after 7 days from implantation for groups G1, G2, G3, at 21 days - for groups G4, G5, G6, and after 42 days - groups G7, G8, G9.

On the day of harvesting, each rat was examined radiologically. Radiological exam was performed using Spectral AMI HTX, Spectral Instruments, with the animals in lateral or dorsal recumbence. A medio-lateral or cranio-caudal radiograph of the hind limb was taken for each subject, focusing on the tibial region.

RESULTS

In G1, two subjects showed a misalignment between the two implants, with a normal position of the spring. All subjects had stable implants and no bone lesions were visible.

In G2 only one subject showed misalignment of the two implants, with a straight position of the spring. None of the subjects showed dislodgement of the implant or visible bone lesions.

In G3, only one subject revealed misalignment of between the two implants, with a normal position of the spring. There were no displacement or bone lesions visible in any of the subjects.

In G4 all subjects revealed stable implants with normal position of the springs. No bone lesions were detected in any subject.

In G5, only one subject showed misalignment of the two implants (fig. 1A), with a normal position of the spring. The implants were stable in all subjects and no bone lesions were detected on radiography.

In G6, all implants were stable except one subject. In one subject the distal implant was dislodged, and the spring was unstressed and curved (fig. 1B).

In G7, all subjects except one subject had a correct position of the implant without visible bone lesions (fig. 1C). The affected subject revealed a tibial fracture with displacement at the insertion point of the distal implant (fig. 1D).

In G8, in one subject the implants were not aligned in the same plane however, but the spring was not rotated, and the implants

were stable. There were no abnormalities found in the rest of the subjects.

In G9, a mild misalignment between the implants was detected by radiography, with a normal position of the spring in two subjects. In one patient, a tibial fracture with displacement at the point of insertion of the distal implant was visible.

The overall mini-implant success rate was 94.1%. In 5.9% of subjects, either distal implant fracture with spring detensioning or distal implant detachment was observed. In control mini-implants, without spring, the overall success rate was 100%.

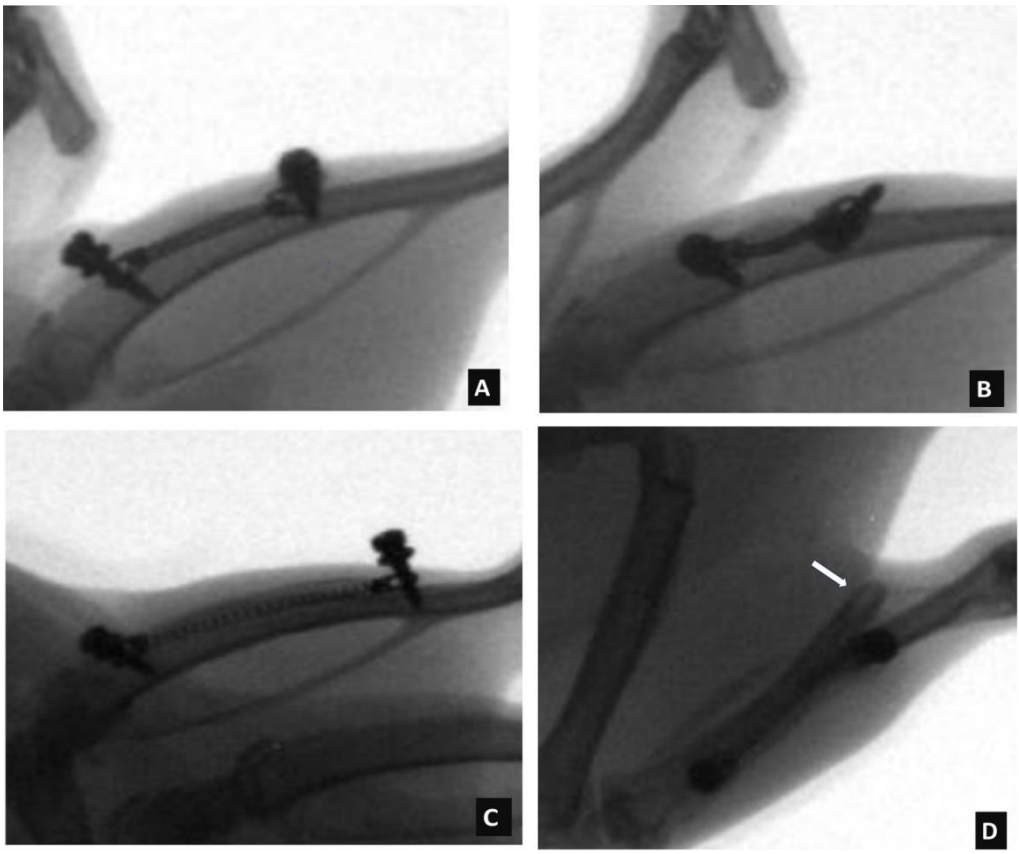

Fig. 1. Radiological images of the hind limb in medio-lateral view in subjects with implants: A. Incorrect alignment of the two implants, but with normal arch position;
B. Distal implant dislocation and arch de;
C. Tibia with implants in normal position and arch under tension;
D. Tibia fracture with displacement, at the distal implant focus;

DISCUSSION

In experimental studies aimed at evaluating orthodontic mini-implants, the use of radiological investigations is relevant both to provide complementary information to other types of examinations (e.g. histological or histomorphometric examinations) and as a single method of analysis (10).

An eloquent example of the value of radiographic examination is the study conducted by the team coordinated by Dhaliwal, which aimed to investigate the osseointegration of mini-implants using histomorphometric analysis. However, after mini-implant placement and suturing, the authors performed radiographs to confirm proper placement of the mini-implants and to observe any bone fractures in the rabbit tibia (10).

Micro-computed tomography (micro-CT) is indicated for further experimental research on the efficacy of mini-implants, as the information on the morphology, structure and density of peri-implant bone tissue is superior to other types of radiological investigations. An experimental study aimed at identifying mini-implant movements in bone and observing the bone remodeling pattern proposes a new experimental animal model, in which mini-implants are inserted into vertebrae, in rats (11). Using micro-CT, the authors recorded volumetric images from the same animal at different times, thus accumulating information on the movements of the mini-implants under the action of orthodontic forces and the changes occurring in the bone structure (11). The results revealed that the mini-implant movements are accompanied by a thickening of the bone, especially in the direction of force loading, which led to a decrease in the mini-implant movement during the experiment (11).

Imaging assessment can also be performed using cone beam computed tomography (CBCT). Recent research in an experimental canine model investigated the role of orthodontic mini-implant placement at different times after lateral incisor extraction (12). The study examined the development of alveolar ridge height, width, and density of the maxillary bone by histological, histomorphometric and imaging analysis. CBCT results showed that mini-implants placed immediately after extraction retained greater alveolar ridge height than mini-implants placed at 6 weeks or in the absence of implant placement (12). Bone density was higher with implants, regardless of when they were placed, compared to bone density in the post-extraction zone without implants (12). Insertion of mini-implants had a positive outcome, preserving post-extraction socket height, increasing bone density and stimulating new bone formation compared to the control area (12).

Not only bone remodeling, bone density or verification of the position of the mini-implant in the bone has been analyzed with radiological studies. Another line of research aimed to assess stability according to the insertion angle of the mini-implant (13). Micro-CT examination of the bone-implant contact area and correlation with the pull-out test showed that stability is influenced by the amount of bone tissue around the mini-implant (13). The obtained data indicated that a maximum amount of bone, i.e. increased stability, can be achieved by inserting the mini-implant at angles between 50° and 70° (1).

The analysis of our results suggests that post-implant fractures, as well as implant dislocation and arch stress relief, occurred because of external factors – namely manipulation or trauma. This assumption is supported by the fact that in most animals the implants remained stable throughout the experiment, without inducing bone damage or dislocation of the implanted system. In addition, all subjects with complications showed a fracture focus at the distal point of implant insertion, an area

where the tibial bone diameter is smaller – which may be explained by reduced bone strength rather than secondary to post-implant osteolysis-type injuries.

CONCLUSIONS

Experimental orthodontic research has the major objective of optimizing orthodontic treatments and increasing the success rate. Imaging exams are valuable tools for analyzing bone remodeling, density, and in vivo structure of bone tissue. Their use, in parallel with histological examination, allows a reduction in the number of animals that will ultimately be sacrificed. Our study confirms the effectiveness of imaging examination in verifying the stability of the implantation stage, as a mandatory step in the subsequent evaluation of morphological changes in peri-implant bone tissue.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

RESEARCH ON THE BIDIRECTIONAL RELATIONSHIP BETWEEN PERIODONTAL DISEASE AND HIGH BLOOD PRESSURE (Abstract): As the importance of the connection between periodontal disease and cardiovascular disease becomes increasingly prominent in medical practice, it is essential to explore this relationship and its implications for patients. The **aim** of this research was to investigate the impact of periodontal disease on the development and progression of cardiovascular disease and to establish that periodontal disease represents a relevant risk factor for the occurrence of cardiac pathologies. **Materials and methods:** A retrospective study was carried out, including 138 consecutive patients who addressed the Dental Education Clinical Base, between November 2021 and November 2023. The patients included in the study were divided into two groups, a group composed of 74 patients (group I: n=74) with periodontitis and a group of 64 patients without periodontitis (group II: n=64). **Results:** Research has revealed that the prevalence and severity of periodontal disease are higher in individuals with hypertension compared to those with normal blood pressure levels. Conclusions: our results argue once again for the assessment of the bidirectional correlation between periodontal disease and hypertension. **Keywords:** PERIODONTAL DISEASE, PERIODONTITIS, HIGH BLOOD PRESSURE, HYPERTENSION, BIOFILM, ORAL MICROBIOTA.

Periodontal disease is considered a chronic bacterial infection characterized by persistent inflammation, degradation of connective tissue, and destruction of alveolar bone (1). It includes gingivitis (where inflammation is limited to the gums and is reversible if the patient maintains good oral hygiene) and periodontitis (a bacterial infection characterized by a destructive inflammatory process due to the action of bacteria and their products, which extends and leads to tissue destruction and alveolar bone resorption) (2, 3).

This condition is primarily induced by

bacteria that form biofilms in the periodontium, leading to inflammatory changes in the tissues that support dental units (3, 4). Diagnosing it is complex and is based on clinical examination, the patient's age at the time of diagnosis, the rate of disease progression, as well as systemic and local factors (5). The global prevalence of periodontal diseases is substantial, affecting a significant portion of the population (6). It is considered a public health issue due to its high prevalence worldwide (7).

From a clinician's perspective, defining periodontal disease is fundamental for understanding and addressing this complex pathology. Periodontitis is a slowly progressive disease and tissue destruction is largely irreversible. In the early stages, the disease is usually asymptomatic, but many patients become aware of it when the condition has progressed far enough to result in tooth mobility. Deep pockets occur as a result of further destruction of the fibers of the periodontal ligament (called loss of attachment) and resorption of the alveolar bone that occurs in parallel with the loss of attachment progress.

These diseases are set up by a chronic inflammatory process, starting with bacterial biofilm forming on tooth surfaces, followed by an inflammatory reaction of the host tissues. The complex interplay between pathogenic microorganisms, host immune response and environmental factors leads to progressive tissue and bone changes and damage that can affect oral and general health (8).

Advanced periodontal inflammation is characterized by gingival erythema and edema, gingival bleeding and recession, tooth mobility, pathological malpositioning of teeth, suppuration of periodontal pockets and tooth loss. The condition is very common, with a frequency of 10-15% in adults in most populations studied (9). Moderate periodontitis is even more common, affecting 40-60% of adults, and severe periodontitis has been identified with the sixth highest prevalence of the disease worldwide (10).

In the detailed evaluation of periodontal disease, it is essential to investigate the typologies and stages of this condition for a proper understanding of the mechanisms involved and the development of appropriate therapeutic strategies (11).

Studies show that periodontitis is a chronic inflammatory condition of the periodontal tissue with a multifactorial etiology, caused, among other factors, by the disruption of the oral biofilm. Key pathogens such as *Aggregatibacter actinomycetemcomitans*, *Porphyromonas gingivalis*, *Fusobacterium nucleatum*, *Prevotella intermedia* and *Tannerella forsythia* (12, 13) can disrupt the oral microbiota, inducing dysbiosis and chronic inflammation of the periodontium. These elements are essential in understanding the complex interactions involved in periodontal disease.

Consequently, a detailed understanding of the various types and stages of periodontal disease is fundamental for clinical and therapeutic approaches, highlighting the complexity of this condition and the necessity for personalized interventions (14, 15). At the EuroPerio's eighth edition in 2019, the Congress of the European Federation of Periodontology, a new classification of periodontal pathology was developed (16).

This classification adopted a staging and grading system for the diagnosis of periodontitis, which, on one hand, records different degrees of disease severity, and on the other hand, the anticipated progression of the condition. Therefore, diagnos-

ing periodontal disease also requires a thorough clinical and radiological evaluation, with modern imaging unequivocally contributing to the correlation between periodontal and systemic status (17).

Recent studies highlight the links between periodontal diseases and systemic conditions, including cardiovascular diseases, showing possible common pathogenic mechanisms (18). Over the past two decades, a substantial number of epidemiological studies have been conducted to investigate the relationship between periodontitis and cardiovascular diseases, making this topic one of the major areas of interest in periodontal research (19, 20).

The etiology and microbiology of periodontal diseases have been extensively studied, shedding light on the complex pathogenesis of these conditions (21). The understanding of the molecular mechanisms underlying periodontal tissue diseases has evolved over the years, providing insights into the inflammatory processes, cytokines and matrix metalloproteinases involved in the progression of the disease (21). In addition, the association between periodontal disease and chronic systemic conditions such as hypertension, dyslipidemia, stroke, myocardial infarction, angina pectoris and diabetes has been explored, revealing a higher prevalence of periodontal disease in individuals with these comorbidities (22, 23).

One third of all deaths worldwide are caused by cardiovascular disease, which is thus the leading cause of death worldwide. Moreover, globally, cardiovascular disease causes more deaths than cancer, chronic respiratory failure and diabetes combined (24).

In addition to their impact on the population as a factor increasing mortality, cardiovascular disease is also a major cause of disability and chronic disease, placing a considerable burden on health systems and the economy.

The association between periodontal disease and cardiovascular disease has been intensively investigated and various theories have been proposed to explain this link. One theory suggests a direct invasion of endothelial cells by periodontal pathogens, while another proposes an indirect pathway by which periodontal disease triggers a systemic inflammatory response (25). In addition, a common genetic basis has been suggested as a possible link between these two conditions (25). These theories collectively emphasize the complex interaction between periodontal and cardiovascular status.

Studies emphasize the strong relationship between periodontal and cardiovascular diseases, focusing on two main directions of this association (26). The first direction suggests that bacteria in the oral cavity may directly exacerbate cardiovascular disease or modify systemic risk factors for cardiovascular disease (26). The second direction emphasizes how chronic periodontal inflammation, viewed as a focus of infection, may increase circulating levels of inflammatory molecules, exacerbating cardiovascular disease (26).

As the importance of the connection between periodontal disease and cardiovascular disease becomes increasingly prominent in medical practice, it is essential to explore this relationship and its implications for patients.

This study proposes to investigate the impact of periodontal disease on the development and progression of cardiovascular disease and to establish that periodontal disease represents a relevant risk factor for the occurrence of cardiac pathologies.

MATERIALS AND METHODS

A retrospective study was carried out, including 138 consecutive patients who addressed the Dental Education Clinical Base, between November 2021 and November 2023.

Inclusion criteria. Patients with gingival diseases not induced by dental biofilm, patients without signs of periodontal disease, patients with gingivitis induced by dental biofilm, patients with periodontitis and patients with periodontitis appearing as a manifestation of systemic diseases.

Exclusion criteria. Chronic alcohol users and patients with other cardiovascular diseases other than hypertension (HT) were excluded from the study. According to the World Health Organization (WHO), there is a significant variation in the prevalence of cases with severe forms of periodontitis in the population, which is approximately 10-15%.

Starting from this aspect, we considered an effect size of 11%, representing the reference prevalence for establishing the minimum sample size, which requires obtaining a minimum volume to ensure adequate representativeness of the patient category.

To achieve this prerequisite, we set a 95% confidence interval. The sample size was determined based on the condition of having a confidence interval smaller than the allowable level of error.

Accordingly, we used the equation:

$$n \geq \left(Z_{\left(1-\frac{\alpha}{2}\right)} \right)^2 \cdot \frac{p \cdot (1-p)}{d^2},$$

where Z = 1.96 for a 95% confidence interval and a minimum error of estimate of 5%. We estimated a minimum sample size of 138 cases.

The patients included in the study were divided into two groups, a group composed of 74 patients (group I: n=74) with periodontitis and a group of 64 patients without periodontitis (group II: n=64).

The primary objective of the study was to assess the correlation between periodontitis and hypertension mediated by a number of risk factors.

Hypertension was considered as a dichotomous dependent variable defined by systolic blood pressure of 140 mmHg or more and/or diastolic blood pressure of 90 mmHg or more and/or current use of antihypertensives.

Data were processed in MS Excel and statistical analysis was performed with SPSS v. 29 program (IBM Ireland Product Distribution Limited, IBM House, Shelbourne Road, Ballsbridge, Dublin, Ireland) and STATA 16 software (StataCorp LLC, 4905 Lakeway Drive, College Station, TX, USA).

The existence of significant statistical differences was considered for a confidence interval of 95%, and parametric or non-parametric tests were applied depending on the characteristics of the variables. Student's t-test, Pearson-χ^2, Fisher's test, Levene's test, ANOVA test, logistic regression and multivariate analysis tests were used.

The threshold of significance was p = 0.05 corresponding to a maximum acceptance error of 5%. Descriptive statistical indicators were calculated for continuous variables (mean, standard deviation, standard error, minimum, maximum and quartile intervals).

Within the descriptive statistics, the values of the location indicators (mean,

median, mode), scattering (dispersion, amplitude) were calculated, we determined, as appropriate, the interval of variation with 95% confidence (for the study of proportions) and within the analysis statistics, we applied tests to determine the regression model, comparison of ANOVA means, the Chi square test (χ^2) for comparing proportions and we tested the sensitivities of the diagnostic methods. This allowed the highlighting of associations, relationships and interdependencies between variables of interest.

RESULTS

From the analyzed database, it has been observed that the prevalence and severity of periodontal disease are higher in individuals with hypertension compared to those with normal blood pressure levels.

Demographic characteristics. In the analyzed cohort, the prevalence of periodontal disease was 53.62% (74 cases). In the studied group, 48 patients with periodontitis manifested as a result of systemic diseases were included (tab. I).

TABLE I.
Study Group Structure Based on Periodontal Involvement

	Count	%
Periodontitis absent	64	46.38%
Without signs of periodontal disease	18	13.04%
Gingival diseases that are not induced by the dental biofilm	25	18.12%
Gingivitis induced by dental biofilm	21	15.22%
Periodontitis present	74	53.62%
Periodontitis	26	18.84%
Periodontitis appeared as a manifestation of systemic diseases	48	34.78%

High blood pressure was found in 67.39% of the cases included in the study (93 cases). The distribution of cases according to the degree of high blood pressure showed a frequency of 18.84% for grade 1 high blood pressure, 28.99% for grade 2 high blood pressure, and 19.57% for grade 3 high blood pressure (tab. II).

TABLE II.
Frequency of high blood pressure in the study group

	Count	%
No high blood pressure	45	32.61%
High blood pressure	93	67.39%
High blood pressure grade 1	26	18.84%
High blood pressure grade 2	40	28.99%
High blood pressure grade 3	27	19.57%
Total	138	100%

The evaluation of the association of periodontitis with the presence of high blood pressure revealed a frequency of 89.19% of cases with periodontitis/periodontal disease that associates high blood pressure. The frequency of cases that associated periodontitis and hypertension (89.19%) was significantly higher (χ^2=34.50, p < 0.001) compared to the frequency of cases without periodontitis with hypertension (42.19%) (tab. III).

The analysis of the frequency of cases according to the degree of hypertension noted in table IV.

TABLE III.

Association of periodontitis with the presence of high blood pressure

		Periodontal disease		Total
		absent	present	
High blood pressure	absent	37	8	45
	%	57.81%	10.81%	
	present	27	66	93
	%	42.19%	89.19%	
	Total	64	74	138
Pearson's chi-squared test: χ^2=34.50, p < 0.001 **Spearman correlation: r=0.5338**				

TABLE IV.

Evaluation of the presence of periodontal disease according to the degree of high blood pressure

		Periodontal disease		Total
		absent	present	
High blood pressure	absent	37	8	**45**
	%	57.81%	10.81%	
	grade 1	18	8	**26**
	%	28.13%	10.81%	
	grade 2	7	33	**40**
	%	10.94%	44.59%	
	grade 3	2	25	**27**
	%	3.13%	33.78%	
	Total	64	74	**138**
Pearson's chi-squared test: χ^2=58.61, p < 0.001 **Spearman correlation: r=0.62649**				

In the context in which the specialized literature mentions a series of risk factors for both periodontitis and high blood pressure, demographic and clinical parameters were analyzed as possible associated risk factors. Thus, they were analyzed as risk factors associated with periodontitis in increasing the chance of high blood pressure.

Gender. The gender of the patients did not present a significant association with

periodontitis, an aspect that demonstrates the homogeneity of the group created by the consecutive introduction of cases according to the inclusion and exclusion criteria in the group. In the analyzed group, the presence of periodontal disease showed a frequency of 54.05% in men and 45.95% in women (tab. V).

TABLE V.
Association of periodontal disease with gender of patients

		Periodontal disease		Total
		absent	present	
Patients gender	male	36	40	76
	%	56.25%	54.05%	
	female	28	34	62
	%	43.75%	45.95%	
	Total	64	74	138
Pearson's chi-squared test: χ^2=0.0668, p =0.7959 **Spearman correlation: r=0.02201**				

The descriptive evaluation of the frequency of periodontal disease cases according to the gender of the patients and the association of high blood pressure revealed a significantly (χ^2 = 4.98, p = 0.03198) higher proportion of male cases associating high blood pressure in the case of periodontal disease.

Age. The age of the patients included in the study group showed an average of 48.57 years (SD – standard deviation = 11.53). The minimum age values were 21 years, and the maximum values were 68 years. It was also noted that 50% of the analyzed patients were younger than 51 years old.

Comparing the values of the patients' age according to the presence of periodontitis, a non-normal distribution was noted. The very high frequency of cases with periodontal disease between the ages of 55 and 60 is noted (tab. VI).

TABLE VI.
Statistical indicators of patients' age according to the presence of periodontal disease

Periodontal disease	Average Age	Average		Dev. std	Min	Max	Q25	Median	Q75
		-95%	-95%						
Absent	42.19	39.58	44.79	10.44	21.00	58.00	32.50	45.00	49.50
Present	54.08	51.89	56.27	9.44	28.00	68.00	50.00	56.00	60.00
All Groups	48.57	46.62	50.51	11.53	21.00	68.00	38.00	51.00	57.00
Test statistic: Mann-Whitney U Test: Z = - 6.4193, p < 0.001 Levene Test of Homogeneity of Variances: F=5.5376, p=0.02004									

Residence. Considering the fact that the literature presents socio-economic status as an important risk factor for periodontal disease, we evaluated the rural residential environment as a possible element that can represent a risk for periodontal disease. This aspect can be explained by the limited access to dental care.

The results indicated an inhomogeneous sample in terms of resident environment (U:

R → 90:48). In order to eliminate this particular aspect of the two analyzed groups of patients, the frequency of periodontal disease was evaluated by referring to the number of patients in each group corresponding to the residence environment.

The analysis demonstrated a significant association (p = 0.0126) of the rural environment of rural residence and the presence of periodontal disease in patients from the analysed group (62.5%). In the group of patients from the urban environment, the presence of periodontal disease was found at 48.89% (tab. VII).

TABLE VIII.

Association of periodontal disease with the domicile of the patients

		Periodontal disease		Total
		absent	present	
Residence	**Urban**	46	44	**90**
		51.11%	**48.89%**	
	Rural	18	30	**48**
		37.50%	**62.50%**	
		64	74	**138**
Pearson's chi-squared test: χ^2=12.332, p =0.0126 Spearman correlation: r=0.3707				

The analysis of the correlation between the presence of periodontal disease, high blood pressure and the gender of the patient demonstrated a significant association explained by the high frequency of cases with periodontal disease, high blood pressure coming from rural areas (62.5%) (tab. VIII).

TABLE VIII.

Association of periodontal disease with high blood pressure and gender of patients

	High blood pressure	Urban	Rural	Total
Periodontal disease absent	HBP absent	26	11	37
		28.89%	22.92%	
	HBP present	20	7	27
		22.22%	14.58%

Pearson's chi-squared test: χ^2 = 8.9718, p = 0.00274 Spearman correlation: r= 0.6225				

DISCUSSION

This result once again argues for the assessment of the bidirectional correlation between periodontal disease and hypertension. The approach in this study of a retrospective analysis will allow the analysis of this correlation only from the perspective of identifying to what extent periodontal disease increases the chance/risk of hypertension.

Over the past twenty years, multiple studies have demonstrated that persons with periodontitis have an increased susceptibility to cardiovascular events, such as myocardial infarction, peripheral artery disease, stroke, and heart failure (HF).

Crucially, pre-clinical research has also corroborated this association. For example, Akamatsu and colleagues showed that periodontal infections caused myocarditis and/or myocardial infarction in mice (17).

While a potential correlation between cardiovascular disease (CVD) and periodontitis has been seen in clinical settings, the specific mechanism that links these two conditions has not yet been fully understood. However, the primary mechanism that explains this association seems to be the spread of oral pathogens into the bloodstream.

For example, bacteremia, which is frequently produced by both non-surgical and surgical dental procedures, is a significant contributor to infective endocarditis in those who are prone to heart disease (18). Therefore, individuals with heart disease who are undergoing dental procedures are offered prophylaxis (18).

The underlying physiological processes responsible for oral health or periodontal disease and hypertension are not thoroughly comprehended. Several studies have indicated that individuals with primary arterial hypertension and poor dental health are more prone to experiencing oxidative stress. This can lead to higher levels of reactive oxygen metabolites, lipid peroxidation, and reduced total antioxidant capacity. This may lead to the deactivation of prostacyclin and nitric oxide (NO). Therefore, an increase in peripheral vascular resistance and hypertension is observed (19, 20).

The correlation between periodontitis and hypertension is crucial, as the advancement of cardiovascular disease is greatly influenced by the level of blood pressure management attained in individuals with hypertension. Fifteen Identifying modifiable risk factors for the advancement of hypertension-induced damage is a top goal worldwide, given its substantial impact on illness, death, and healthcare costs.

Additionally, our investigation was subject to many constraints. The design of our study precludes us from making causal inferences about our findings, as we lack information on the time sequence of the relationship between periodontal disease and blood pressure. Nevertheless, hypertension is unlikely to be a direct cause of periodontal disease.

Additionally, our study was constrained by a small sample size, which resulted in insufficient statistical power for conducting subgroup analyses on specific groups such as diabetics, individuals who have never smoked, and individuals who are former or present smokers.

Although our study has limitations, it clearly shows a potential significant connection between periodontal health and the control of blood pressure. This finding could have a significant influence on public health, particularly among the older popu-

lation. Due to the constraints of our study, additional research is required to validate this correlation in different populations.

CONCLUSIONS

The link between periodontal disease and cardiovascular disease is multifaceted, involving mechanisms such as inflammation, common genetic factors, and systemic responses to oral pathogens.

The results of the retrospective study, together with the findings from various studies, support a significant association between these two conditions, underscoring the importance of considering periodontal health in the management of cardiovascular disease.

Understanding and addressing the interaction between periodontal disease and cardiovascular health is critical to comprehensive patient care and disease prevention strategies.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

PLASMA VITAMIN C LEVELS ASSOCIATED WITH THE DIET AND SUPPLEMENT CONSUMPTION (Abstract): The aim of this study is to show the amount of vitamin C in the plasma as a consequence of lifestyle changes. **Materials and methods:** The level of vitamin C in plasma were determined prior to the study (T1), and after five months (T2). Moreover, a medical record was carried out as well as a questionnaire on general eating habits and specific consumption of food rich in vitamin C. Both of them were completed before and after five months. In addition, related anthropometric analyses were carried out. **Results:** The results of the first determination of vitamin C level in plasma were between 1.0 and 16.0 mg/L and the results of the second determination of vitamin C in plasma were between 4.9 and 14.1 mg/L. Furthermore, it was identified that 50% of the subjects had a low fruit intake. Raw vegetables were consumed by fewer subjects, the intake being higher during the main meals. **Conclusions:** The correlation of plasma vitamin C with the eating habits of the subjects involved in the study points out an interdependence between the consumption of fruit and vegetables and the level of vitamin C in plasma. **Keywords:** VEGETABLES, PLASMA VITAMIN C LEVEL, HUMANS.

INTRODUCTION

Fruits and vegetables are known to possess a plethora of benefits which can improve human health. Observational studies pointed out that a high consumption of fruit and vegetables is associated with a lower risk of developing cancer (1, 2, 3, 4, 5) thus, being beneficial for the prevention of cardiovascular diseases as well (6, 7, 8). The potential benefic role of fruit and vegetables was attributed to the component specific effect, such as vitamins, minerals, food fibers, and a range of secondary metabolites (phytochemicals), responsible for color, flavor, and taste (9).

Previous studies pointed out that the plasmatic concentrations of carotenoids and vitamin C increased both the following and the intake of fruit and vegetables (10, 11).

The correlation between the level of the plasma vitamin C and the eating habits was studied by Wrieden *et al*. in 2000 (12),

concluding that the consumption of fruit and vegetables three or more times a day can significantly increase the level of vitamin in plasma. Furthermore, it was observed that a portion of freshly squeezed citrus juice equals two fresh fruit or vegetables consumed during meal times (13).

The presence of compounds with an antioxidant activity in the composition of fruit and vegetables, which represent the basic food intake of the population living in the tropical area, was studied by Jdeani *et al*. in 2021. They concluded that although these could satisfy an important part of a human's nutritional needs, an increase in population would lead to an increase of the dependence on supplements with synthetic antioxidants, all these with the purpose to reduce terminal and degenerative diseases (14).

The compounds with antioxidant activity present in the composition of fruit and vegetables, such as vitamin C, vitamin A, vitamin E, and carotenoids have a benefic effect, leading to the strengthening of the human immune system and the reduction of risks associated with the development of a chronic disease (14, 15). Furthermore, vitamins C, A, E, carotenoids, fruits, and vegetables are rich in a variety of polyphenols and minerals that exhibit a significant antioxidative activity. These compounds, including flavonoids, tannins, and lignans, contribute to the reduction of oxidative stress and play a vital role in strengthening the immune system as well as in reducing the risk of chronic diseases. Additionally, minerals such as selenium and zinc are crucial cofactors for antioxidant enzymes. Acknowledging the full spectrum of these nutrients underscores the comprehensive health benefits of a diet high in fruits and vegetables.

Vitamin C (ascorbic acid) is a micronutrient with a very important role in the well-functioning of the human organism, being involved in over 300 metabolic functions (1, 2, 3, 5). The sustainability of vitamin C is explained through its capacity to destroy and neutralize free radicals and oxidative stress (16, 17), taking part in a series of redox reaction at cellular level (18). It has an anti-infectious protection role (19, 20), it acts beneficially to combat *Helicobacter pylori* (1); it prevents cancer incidence (19, 21), having anti-inflammatory (21, 22), anti-angiogenic (14, 23-26), and anti-tumoral (15, 19) properties; it participates in the synthesis of the bile acids, it prevents the development of coronary diseases and atherosclerosis (1, 2, 6-8, 14-17, 20-24, 27-31); it diminishes the level of reactive protein C (2, 14, 24, 29-31); it facilitates the elimination of heavy metals from the organism by neutralizing them (1, 6-8, 14-17, 20-24, 27, 29, 31). It plays an important part in stimulating the biosynthesis of stress adjusting hormones, being involved in the production of antistress hormones and of interferon (an important protein of the immune system) (1); it sustains the functioning of the adrenal gland (1), and it participates in the metabolism of the collagen (18-20, 32-35).

The classical diseases determined by a lack of vitamin C is scurvy, which develops due to the role played by the vitamin in the post-translational modification of collagen. An excessive intake of vitamin C can cause diarrhea, abdominal bloating, over-absorption of iron, hyperoxaluria (in dialyzed patients), and hemolysis (in patients with a deficit of glucoses-6-phosphate dehydrogenase). A tolerable upper intake level for vitamin C is equal to 2000 mg/day as it was established by the Council for

Food and Nutrition in 2000 (27).

The recommendations for the vitamin C intake can be found in the Recommended Dietary Allowances (RDAs), developed by the Food and Nutrition Board of The National Academies of Sciences, Engineering, and Medicine, The Recommended Daily. The dose - the average daily intake necessary to satisfy the nutritional need of almost all healthy individuals and which is often used to plan nutritive adequate diets for individuals and which varies according to age and sex - is of 90 mg for men and 75 mg for women (with an additional quantity of 35 mg for smokers). For these doses the bio-availability of vitamin C is of almost 100% (28).

Most vertebrates and invertebrates have the ability to synthesize vitamin C while the human body does not have this capacity. The inability to synthesize vitamin C is due to mutations in the L-gulono-γ-lactone oxidase (GLO) gene.

GLO encodes the enzyme that is responsible for catalyzing the last step in vitamin C biosynthesis (10, 12, 36).

For this reason, the level of this vitamin in the human organism depends entirely on the exogen vitamin sources (1-6, 8, 10, 12-24, 25, 28-32, 34-36) which include fruit and vegetables (20).

Since fruit and vegetables are a primary source in the diet with vitamin C, the plasmatic level of vitamin C is considered a good surrogate or predictor of vitamin C intake. The correlation can be affected / influence by the presence of external factors such as: the bioavailability of the vitamin, the absorption conditions, stress, the food processing degree and the conservation period or even certain errors in the reporting the level of vitamin C (23, 27, 28).

The purpose of the present study was to measure the plasma levels of vitamin C in a group of volunteers, on the basis of vitamin C consumption from diet and / or supplements.

This means increasing the intake of vitamin C-rich fruits and vegetables or using supplementation. The objectives of the study were to: determine the subjects' baseline health and lifestyle; monitor the intake of foods rich in vitamin C ; inform the subjects on vitamin C as well as on the aim of the study; tailor individual diet plans; group subjects by initial vitamin C levels so as to perform targeted interventions; give the subjects autonomy by allowing them to withdraw from the study at any time; measure the impact of the interventions on the levels of plasma vitamin C.

MATERIALS AND METHODS

Subjects and study protocol

In this study, initiated in January 2023 in Arad County, we engaged a large group of subjects via their general practitioners in order to participate in a dietary intervention aimed at optimizing their plasma vitamin C levels through an increased consumption of vitamin C-rich fruits and vegetables or supplementation. The selection of the subjects was a multistage one, beginning with applying a comprehensive questionnaire on health status, psychological, and medical history, lifestyle habits including substance use, ongoing medical treatment, and physical activity levels to gather preliminary information for the study.

Subsequently, we monitored subjects who regularly consumed fruits and vegetables high in vitamin C - such as black currants, kiwis, lemons, strawberries, oranges, tangerines, grapefruits, melons, papayas, and mangoes.

Upon selecting the subjects, we provided them with detailed information about the aims of the study, the role of vitamin C in health, and the effects of its deficiency or excess. After this phase, a part of the selected subjects chose not to proceed due to personal reasons. The remaining subjects underwent anthropometric measurements in order to tailor the diet plans that were to be followed for the subsequent five months. The plans were based on an intake of 2,000 kcal/day, incorporating the necessary vitamin C dosage and macronutrients as advised by a dietician.

Finally, it was pointed out that all group subjects, comprising 20 women and 22 men, aged between 20 and 45 years (mean age of 34.19±7.68), were in good health and not under any medical treatment during the selection phase. They were categorized based on initial plasma vitamin C levels as follows: below the reference minimum value, within the average range, or above the maximum reference level.

Nutritionists, dieticians, and physicians tailored recommendations for each category, leading to the formation of three groups: one on a specific diet, another on slow-release vitamin C supplements 1000 mg per day in the morning, and the third on a combination of both interventions. Subjects had the autonomy to withdraw at any point upon notification.

The second vitamin C measurement occurred approximately five months later, with the timing slightly varying among subjects. Post-second sampling, we conducted individual discussions regarding dietary adherence, supplement intake, and new anthropometric measurements, along with a questionnaire on food consumption during the study.

In the last stage, we analyzed the collected data, ensuring the confidentiality of personal information. This comprehensive approach allowed us to consider both the subjects' therapeutic needs and personal preferences in order to enhance the plasma vitamin C levels effectively.

Criteria for inclusion:

- Age between 20 and 45 years
- Good health condition, not under medical treatment, at the time during selection the selection trail

Exclusion criteria:

- Individuals who opted out after the first stage focused on delivering them information on the study
- Any major health condition that could affect the absorption or metabolism of vitamin C, such as smoking, regular alcohol consumption, supplement intake.

The study was carried out in accordance with the instruction given at the Helsinki Declaration and all the procedures which involve human subjects were approved by the Human Research Ethics Committee. It was agreed to carry out the study and have its results published by the Scientific Research Ethics Committee of the "Vasile Goldiș" Western University of Arad, Romania under No. 4/13.01.2023.

Determination of vitamin C Level in Plasma

The samples were collected either at the general practitioner's private office in Arad, Romania or in a laboratory of medical analysis, located in Arad, Romania, according to the possibility and the preference shown by each subject. The samples collected at the doctor's private office were collected by the staff belonging to the medical analysis laboratory which ensured the optimum transport conditions. The actual determination of the plasma level of vita-

min C was carried out in Germany and the results were delivered after 10 to 12 days after the moment of the sample collection.

The method used to determine the level of the vitamin C in the plasma was the High-Pressure Liquid Chromatography (HPLC) connected to an electrochemical detector by complying to the protocols in the medical analysis laboratories (23, 30, 31).

The volunteers were asked to avoid alcohol consumption 24 hours before the sampling process and do not eat 12 hours prior to the blood collection process. The blood collection process was conducted in the morning (30).

One milliliter of venous blood was collected from the subjects *à jeun* (they subject did not eat anything prior to the blood collection). The blood was collected in vacutainer collection containers which contained lithium heparinate as an anticoagulant. After sampling, the plasma was separated through spinning and it coagulated immediately (it stable one month if kept at temperature of -20°C); the recipients were covered with an aluminum wrap to protect it from light; in the case of the sample collected outside the laboratory, they were transported in the recipient for the frozen samples. The samples, in which a highly hemolyzed, lipemic or unfrozen, unprotected from light specimens were observed, were rejected (30). The reference values are comprised between 4.6 and 14.9 mg/L (30).

Plasma values of < 3 mg/L point out deficiencies of vitamin C and a concentration of < 0.2 mg/L suggest the presence of scurvy. Low plasmatic levels appear in malabsorption, alcoholism, pregnancy, hyperthyroidism, kidney failure, and in smokers.

Limits and interferences may appear after the ingestion of ascorbic acid. The plasmatic values increase rapidly in 1-2 hours and reach a maximum concentration after 3 or 6 hours from consumption. The testing of the subjects who use vitamin supplements may indicate a higher plasmatic level of the vitamin (31).

Statistical analyses

The statistical tests used in this study were selected by taking into consideration data distribution and the specific research questions addressed.

All statistical analyses were performed with the IBM *SPSS Software version 27*.0 (IBM Corp, New York, USA). Discrete variables were presented as medians along with their minimum and maximum values. Continuous variables were reported as means with standard deviations (SDs). Due to the small size of the sample and the distribution of the data, non-parametric tests were used. Specifically, the Kruskal-Wallis Test was used to evaluate the significance of differences between the studied variables, with a p-value of < 0.05 considered indicative of substantial differences.

In addition to these statistical analyses, descriptive statistics for the methodological validation, including the limit of detection (LOD) and limit of quantification (LOQ), were calculated to ensure the reliability and accuracy of the analytical methods used. The LOD was determined on the basis of the lowest concentration of analyte that could be reliably detected but not necessarily quantified, while the LOQ had the lowest concentration that could be reliably quantified with acceptable precision and accuracy.

RESULTS

Two sets of sampling were made in order to determine the plasma vitamin C: the

first sampling was carried out after the selection of the subjects (Time 1) and the second one after an average period of 5 months (Time 2) (figs. 1 and 2).

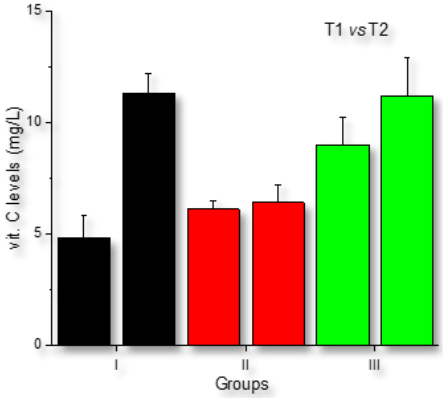

Fig. 1. Subject average vitamin C levels for every group between Time 1 (T1) and Time 2 (T2)

Based on the results of the study, the subjects were divided into three equal groups group, formed of individuals whose plasma vitamin C levels fell on the lower end of the minimum reference values or were below the limit; group II, formed from those subjects whose plasma vitamin C levels were within the normal reference range; and group III, comprising those subjects whose plasma vitamin C levels exceeded the maximum reference range (fig. 1).

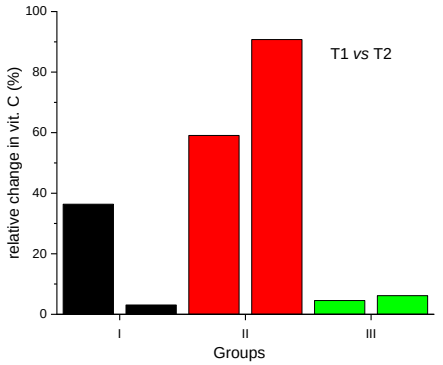

Fig. 2. The changes in plasma vitamin C levels from Time1 (T1) to Time2 (T2) for each group

The questioning of the subjects involved in the study was conducted, both at the time T1 and T2. This questionnaire was completed in relation to the consumption of vegetables and fruit with a high level of vitamin C or other vegetables and

fruit with vitamin C content, consumed frequently, for both moments (figs. 3 and 4).

In figure 3, it can be observed a comparison between the consumption of fruit and vegetables during the first examination and the end of the present study. There were found significant differences between the values at the respective moment ($p< 0.001$).and not found important differences between the values at the end of the present research ($p= 0.560$).

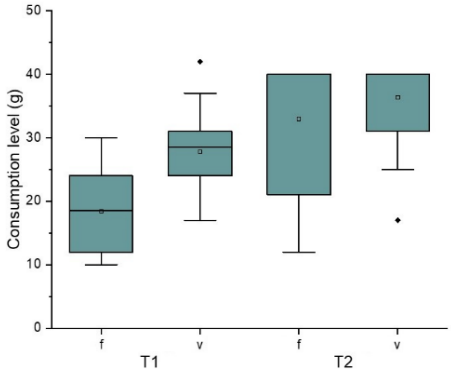

Fig. 3. The ranges related to the consumption of Fruit (a) and Vegetables (b) at Time 1 (T1) and Time 2 (T2), the black line is an indicator of the model

The result of the first collection of plasma vitamin C related to the consumption of vegetables and fruits, from the same period, depending on the group is rendered in fig. 4.

In figure 4, it can be observed a comparative presentation between plasma vitamin C level and the consumption of fruit and vegetables during the first examination. There were found important differences between the values at the respective moment ($p< 0.001$).

The result of plasma vitamin C collection, at the end of the study, compared to the consumption of vegetables and fruit from the same period, depending on the group, is rendered in figure 5.

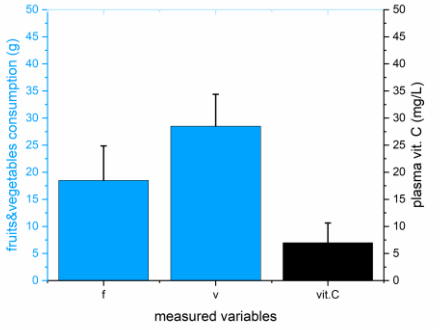

Fig. 4. The consumption of fruit and vegetables as related to vitamin C level at T1 (mode values ± SD)

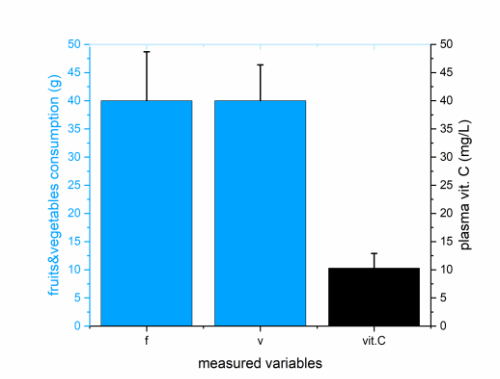

Fig. 5. The consumption of fruit and vegetables as related to vitamin C level at T2 (mode values ± SD)

Figure 5 presents, in a comparative manner, the plasma vitamin C level and the consumption of fruit and vegetables at the end of the study. There were found important differences between the values at that moment ($p < 0.001$).

DISCUSSION

Determination of the plasma vitamin C and its development

The results of the first plasma determination of vitamin C are comprised between 1.0 and 16.0, while the results of the 2nd plasma vitamin C determination are comprised between 4.9 and 14.1 (figs. 1, 2, 4, 5).

The time period between the two analyses is of approximately 5 months, with an insignificant error margin, during which there was a considerable increase in the plasma vitamin C level in 72.73% of the subjects involved, and which was represented by a total increase of 36.59% in the plasma vitamin C level, although 9.09% of the subjects maintained their plasma vitamin C level while 18.18% had experienced a decrease in their plasma vitamin C level.

Ways to consume vitamin C and their subsequent results

It is worth pointing out that 14 subjects agreed to integrate a proper diet into their daily life, other 14 subjects opted for both diet and additional vitamin C consumption, and 14 subjects opted strictly for the consumption of food supplements. During the discussions carried out with the subjects, it was observed a general belief that it is an easier option to solve health problems by consuming food supplements and medicine, than by trying to change one's eating habits and lifestyle.

The maintenance and decrease of the plasma vitamin C level, in most subjects, can also be the result of the fact that the vitamin C content in food is not stable. Most fruit and vegetables are harvested before ripening, so they do not benefit from all the nutritional elements, which would accumulate from soil, rain and sun action. Moreover, groups of vegetables and fruit (especially those consumed in the area and during the period of the study) are grown in greenhouses. Therefore, not enough vitamin C accumulates in the respective food items, or they are stored for a longer period of time. This aspect leads to the loss of vitamin C from the food items.

One of the decreases in the plasma vitamin C level was due to the fact that one person did not administer vitamin C for personal reasons. This aspect was reported

only at T2.

The majority of subjects who opted for vitamin C intake from food supplements had a considerable increase in the plasma vitamin C level. In addition, the subjects who opted for both the diet and the additional consumption of vitamin C from food supplements had considerable increases in the plasma vitamin C level (fig. 1).

This increase is due to a high intake of vitamin C either from food or dietary supplements or both. It can also be the result of the intervention made by nutrition specialists, who gave the right recommendations to each person and offered support throughout the study.

Analysis of eating habits

Habits Related to Fruit Consumption

Although most subjects prefer fruit, their consumption is reduced both at breakfast and lunch. They are usually served as a snack. Fruit was initially consumed a maximum of 1-2 times a day, and 50% of the subjects questioned admitted to have never consumed certain fruit. It was also identified that 50% of those questioned had a low fruit consumption. During the study, fruit consumption increased considerably, due to diet recommendations and explanations provided by the dietician.

Habits Related to Vegetable Consumption

At the beginning of the study, raw vegetables were consumed by a smaller percentage of subjects in comparison with fruit. Furthermore, their consumption was higher during main meals, most subjects refusing to serve vegetables as a snack. The majority of subjects consume vegetables once or twice a day. Among the subjects questioned, 41% have never consumed or very rarely consumed raw vegetables. In most cases, vegetables are prepared for consumption through thermal preparations, an aspect that can lead to the loss of vitamin C content in food.

The subjects' favorite fruit were oranges, tangerines and lemons. The exotic fruit such as papaya and mango as well as strawberries which were out of season (tab. I) registered low consumption values.

TABLE I.

Comparative table on the consumption of fruits with high vitamin C content

FRUIT (g)	Time 1	Time 2
Kiwi	53	76
Strawberries	28	68
Oranges	72	84
Red Grapefruit	52	75
Papaya	3	61
Currants	22	62
Lemons	70	84
Melon	21	68

The preferred vegetables with a high content of vitamin C were bell peppers and tomatoes (mainly consumed raw), potatoes, cabbage, parsley, and peas (consumed in cooked form, included in the main meals), of which parsley and cauliflower were eaten with an increased frequency (tab. II).

TABLE II.

Comparative table on the consumption of vegetables with a high content of vitamin C or with a low content of vitamin C but largely consumed

VEGETABLES (g)	Time 1	Time 2
Cabbage	64	80
Broccoli	34	70
Potatoes	92	93
Bell Pepper	65	82
Parsley	111	95
Cauliflower	49	75
Tomatoes	52	79
Brussels Sprouts	16	67
Spinach	54	77
Peas	75	82

Figure 6-a comparatively presents the consumption of fruits with high vitamin C content between T1 and T2. A significant difference was found between the consumption of the previously mentioned fruits in the two moments (p= 0.009). Figure 6-b comparatively presents the consumption of vegetables with high vitamin C content between T1 and T2. A significant difference was found between the consumption of the mentioned vegetables in the two moments (p= 0.026).

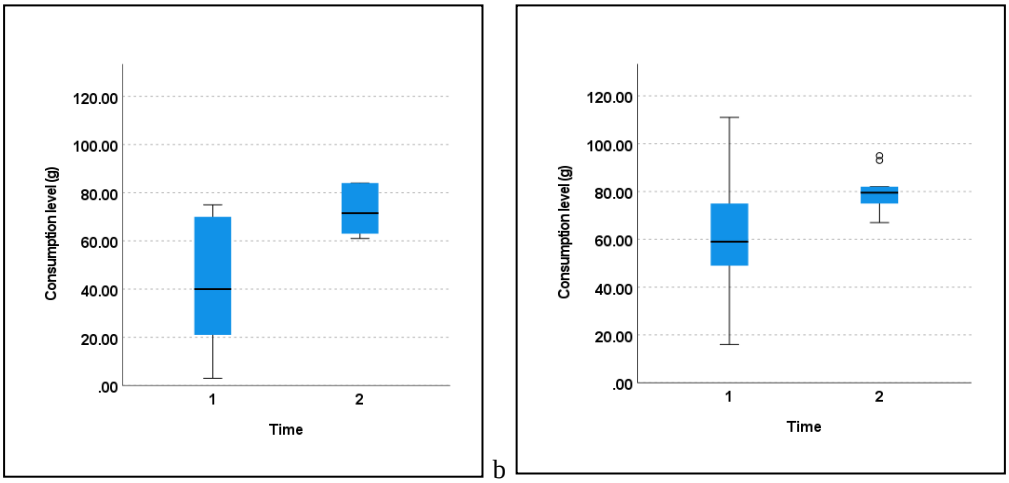

Fig. 6. Comparative consumption of fruits-a / vegetables-b with high vitamin C content between the two questionnaires (the black line is an indicator of the model)

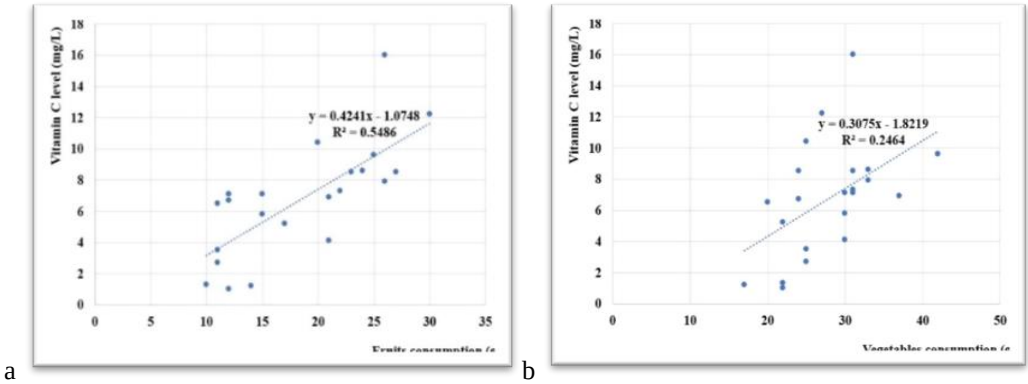
Table III presents a statistical correlation between the plasma vitamin C level and the consumption of fruits and vegetables at the beginning and at the end of the research.

TABLE III.

The values of Spearman correlation coefficient (rho)

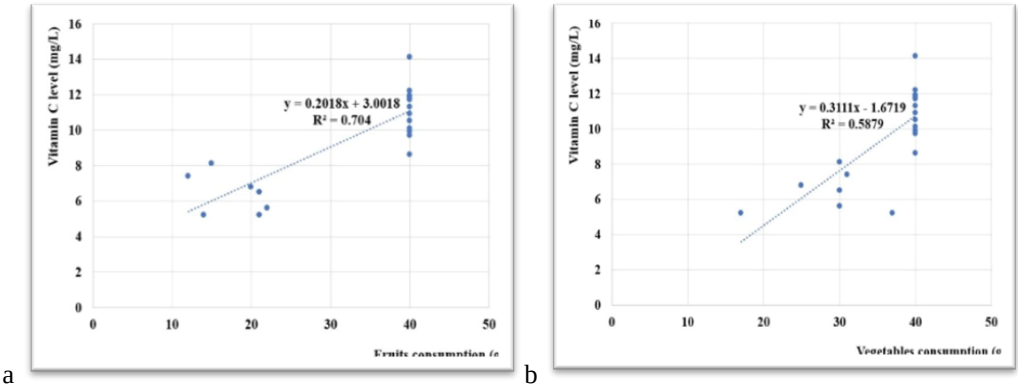
The beginning of study		The end of study	
Fruits *vs.* vitamin C	Vegetables *vs.* vitamin C	Fruits *vs.* vitamin C	Vegetables *vs.* vitamin C
0.791 (p< 0.01)	0.601 (p= 0.003)	0.777 (p< 0.01)	0.795 (p< 0.01)

The values in tab. III present a strong correlation between the consumption of fruits and the level of plasma vitamin C at the beginning of the research and a medium correlation between the consumption of vegetables and the level of plasma vitamin C. At the end of this study, there were found significant strong correlations between the consumption of fruits and vegetables and the level of vitamin C. All these results demonstrate that the consumption of fruits and vegetables which have a high content of vitamin C lead to enhanced levels of this vitamin in human plasma.



a b

Fig. 7. Correlations between the consumption of (a) fruits and (b) vegetables *vs.* the vitamin C level at T1



a b

Fig. 8. Correlations between the consumption of (a) fruits and (b) vegetables *vs.* the vitamin C level at T2

Figures 7 and 8 reveal positive correlations between the consumption of fruits and vegetables and the discovered vitamin C levels.

Some subjects consumed certain fruit and/or vegetables in higher amounts while barely or not at all consuming the others. This aspect changed for most individuals, once with the intervention of the nutritionist, who recommended reducing the consumption of some frequently consumed foods and the intake increase of other fruit and vegetables, thus diversifying the diet of the subjects involved in the study.

It was also observed that women have higher concentration of plasma vitamin C than men. However, the reasons of this observation need further elucidation studies. The results of the study point out that the lower plasma vitamin C concentrations in men compared to women, can be explained due to the higher fat-free mass in men. A special characteristic can be made by a varied series of potential factors such as age, anthropometric variables, the body composition (the total antioxidant status), the intake of vitamin C, lifestyle, the consumption of alcohol, smoking and the phys-

ical activity level (34).

A very slightly increased trend towards the consumption of fruits and vegetables was found at women from Group I and III, but the differences between the men and women was not significantly (p= 0.104). No important difference was also found between men and women in the case of the vitamin C plasma levels for the entire group (42 subjects).

However, our intention was to assess the impact of increased vitamin C intake on plasma vitamin C levels within a real-world setting, within which the subjects were not restricted from their usual lifestyle choices. This approach aimed to assess the practical applicability of dietary recommendations in a non-clinical environment. However, we recognize the limitations of this design and we acknowledge the importance of a control group in clinical research in order to establish a baseline for comparison. Particularly, in our study, this lack was replaced by the following: comprehensive health and lifestyle questionnaires applied in order to establish a detailed baseline for each subject, thus allowing a comparison between the individual outcomes and their own starting points; findings are discussed in the context of current literature in the domain, allowing for indirect comparisons to studies that included control groups. We are planning follow-up studies that will incorporate a control group. This will enable us to validate and compare the results obtained in the current study.

CONCLUSIONS

An important and potential limitation of the current study is the maximum level of fruits and vegetables consumption that was previously established in questionnaires at 40 g.

Although subjects who consumed minimum quantity of fruit and vegetables were chosen for the study, it was identified that the individuals had plasma vitamin C below the reference level (10% avitaminosis C, 28% hypovitaminosis C, 57% in normal limits and almost 5% hypervitaminosis C).

Following the study, a considerable increase in the plasma vitamin C level was achieved, in 72.73% of the subjects. Thus, it was obtained a more appropriate integration within the reference values. This is represented by a 36.59% increase in plasma vitamin C.

The diet group had a smaller increase in plasma vitamin C, and a significant decrease in certain individuals. The group with supplements had a greater increase in plasma vitamin C level and a small decrease in certain individuals. The group following a diet based on supplements had a significant increase in plasma vitamin C levels while no decreases were recorded. In conclusion, vitamin C associated with a proper diet can achieve the therapeutic objectives in a shorter time, than the separate prescription of various diets or supplements, even in healthy subjects. These aspects can indicate that food no longer has the same vitamin C content, raising an alarm signal about the way in which these food items are produced.

Following the study, a capping of the plasma vitamin C level was observed, which may indicate that the surplus of vitamin C is eliminated from the body through urine, but may also highlight a resistance of the body towards the accumulation of the vitamin C. However, further studies are needed in this field.

Other limitations of the present study

include the absence of the anthropometric measurements, the constraints imposed by the small size of the group, the subjects' voluntary retreat from the research, and the methodological challenges.

The plasma vitamin C level is very little influenced by the general daily consumption of products with a high vitamin C content. This aspect that may be due to: the frequency and number of products consumed and which have a high vitamin C content; the eating habits, the way the food is consumed (raw or thermally prepared) as well as the production and supply chain.

Instead, the plasma vitamin C level can be influenced by long-term diet, with regular consumption of food items containing vitamin C. In most cases it can also be influenced by the consumption of food supplements, thus obtaining faster results. However, the best results regarding the increase of plasma vitamin C levels can be obtained by associating a healthy diet with the consumption of vitamin C food supplements.

Since the adequate consumption of vitamin C (and vitamins in general) is very important, it is important to choose suitable food sources that ensure an adequate exogenous intake. In this sense, there is a need to educate the population and its orientation towards local producers and towards products that are as natural as possible, harvested when mature, grown in gardens or open air, but also towards specialists in the field of nutrition and dietetics, who can offer suitable recommendations and necessary support.

INFORMED CONSENT STATEMENT

Informed consent was obtained from all subjects involved in the study. Written informed consent was obtained from all subjects/patients.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

IMPROVING BREAST CANCER MANAGEMENT: A QUESTIONNAIRE-BASED STUDY ON PREVENTION AND DIAGNOSIS AMONG FAMILY DOCTORS AND SPECIALISTS IN NORTH-EASTERN ROMANIA (Abstract): This study **aimed** to analyze the knowledge, clinical practices, and administrative aspects related to breast cancer care among family physicians and specialists in North-Eastern Romania. **Materials and methods:** A structured questionnaire was applied to a total of 200 healthcare professionals, including surgeons, oncologists, radiologists, gynecologists, and general practitioners. Key findings revealed significant deficiencies in screening awareness, interdisciplinary collaboration challenges, and limitations in patient education and reimbursement processes. **Results:** The study suggests the urgent need for a better integration between specialists and primary care providers, the development of enhanced educational programs, and improved access to screening and diagnostic services. **Conclusions:** Addressing these barriers may contribute to more effective breast cancer prevention, early detection, and management in Romania. **Keywords:** BREAST CANCER, QUESTIONNAIRES, PREVENTION.

INTRODUCTION

Breast cancer remains one of the leading causes of cancer-related morbidity and mortality worldwide. In Europe, it is the most commonly diagnosed cancer in women, accounting for nearly 29% of all female malignancies (1). Despite improvements in early detection and treatment, disparities in survival rates persist, with lower survival observed in Eastern European countries, including Romania (2).

The etiology of breast cancer is multi-

factorial, influenced by genetic, hormonal and environmental factors. The increasing prevalence of obesity, physical inactivity, late childbearing, and high-fat diets has contributed to a rising incidence rate (3). Additionally, healthcare disparities, low screening awareness and inadequate funding for national programs further contribute to Romania's high mortality rates (4).

According to the GLOBOCAN 2020 report, breast cancer remains the most frequently diagnosed malignancy worldwide with an increasing incidence trend (5). In Romania, breast cancer ranks among the top causes of oncological mortality, with early detection remaining a major challenge due to a lack of well-structured national screening programs and limited public awareness campaigns (6). Additional barriers in the Northeastern Romania healthcare system-such as inadequate reimbursement policies and poor coordination between specialists and primary care physicians-further delay timely diagnosis and treatment (7).

This study aims to evaluate the current state of breast cancer management in North-Eastern Romania by assessing the knowledge, practices and perceptions of family physicians and specialists while also seeking to identify gaps in early detection, patient education and healthcare infrastructure in order to formulate valuable recommendations for policy improvements.

MATERIALS AND METHODS

A four-step approach was used in this study:

1. *Questionnaire development:* Structured, self-administered questionnaires designed following a literature review and expert input (8). The survey included questions on screening practices, patient management, interdisciplinary collaboration, and administrative challenges.

2. *Data collection:* The survey was distributed to 200 healthcare professionals across various medical specialties, including surgery, oncology, radiology, gynecology, and general practice.

3. *Data analysis:* Responses were systematically categorized and analyzed using descriptive statistics to identify trends in clinical practice, screening recommendations, and interdisciplinary collaboration.

All healthcare professionals provided informed consent regarding data confidentiality and privacy. The data were processed using *Microsoft Excel* 2010.

4. *Validation:* The results were reviewed by experts to ensure accuracy and relevance (9).

The questionnaire assessed various aspects of breast cancer screening, diagnosis, treatment, and follow-up, with a particular focus on healthcare system challenges and opportunities for improvement. The statistical analysis of our study provided a comprehensive understanding of the collected data. Using the descriptive statistics function, we computed key statistical measures, including the mean, mode, skewness, and kurtosis, to assess the distribution and shape of the data.

RESULTS

The study identified several key aspects of breast cancer management among healthcare professionals in North-Eastern Romania.

The demographic structure of the surveyed group highlighted that most participants were young adults (36-40 years old - 32.42%) and women (64.1%). The sample consisted of a diverse group of 100 doctors from various medical specialties, including general and plastic surgery, oncology, radiology, gynecology, and radiotherapy, along with 100 general practice doctors (tab. I, fig. 1)

TABLE I.

Demographic and socioeconomic characteristics.

Characteristics	Frequency %
Age (years)	
31-35	24.27
36-40	32.42
41-45	18.92
46-50	10.84
51-55	13.55
Gender	
Female	64.1
Male	35.9

General surgery	29.4
Plastic surgery	4.7
Medical oncology	27.6
Gynecology oncology	14
Medical radiology	16.6
Radiotherapy	7.7
Family medicine	100

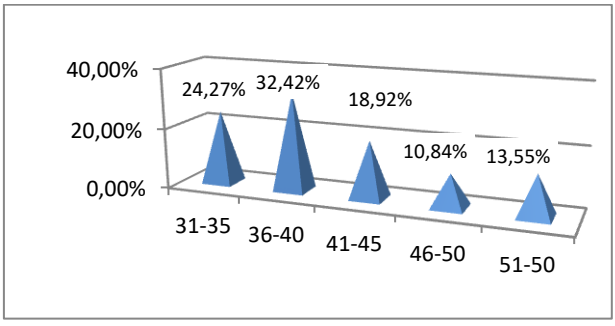

Fig .1. Age histogram

Clinical knowledge and practices among specialists

Most specialists (61.5%) reported frequent encounters with suspected breast cancer cases. However, 76.9% of respondents considered cases in women under 30 to be rare. The most common reasons for referral were the presence of breast lumps (97.4%), abnormal nipple discharge (41%), and a family history of breast cancer (28.2%). In younger patients, breast lumps remained the predominant reason for referral (87.2%).

Regarding diagnostic methods, mammography, breast ultrasound, and biopsy were recommended in over 92% of cases. For younger patients, ultrasound (92.3%) and MRI (74.4%) were preferred over mammography (43.6%). Fine needle aspiration biopsy (48.7%) and core needle biopsy (46.2%) were used with similar frequency.

Knowledge and education among family physicians

Most family physicians rated their knowledge of breast cancer as 'very well-informed' (63.5%) or 'moderately informed'

(35.6%). However, 57.7% had never attended courses or workshops on breast cancer prevention and diagnosis. Additionally, 53.8% of respondents believed that information on breast cancer was not sufficiently available for family physicians.

Diagnosis and recommendations among specialists

The diagnosis of breast cancer following biopsy was reported as frequent or very frequent by 59% of respondents. The most important criteria for monitoring patients included lymph node involvement (97.4%), tumor size (87.2%), and distant metastases (82.1%) (fig. 2).

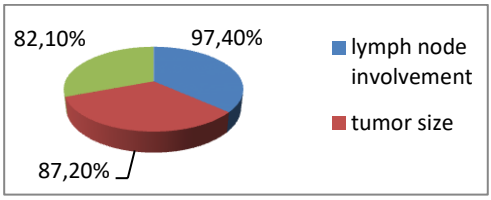

Fig. 2. The most important criteria for monitoring patients

Treatment recommendations were primarily surgical (94.9%), followed by chemotherapy or radiotherapy (92.3%) and hormonal therapy (82.1%).

Screening and diagnostic practices among family physicians

The majority of respondents (46.2%) recommended initiating mammographic screening between 40 and 50 years, followed by 31.7% who supported screening between 30 and 40 years. Breast ultrasound (94.2%), mammography (91.3%), and self-examination (89.4%) were the most frequently recommended screening modalities. MRI was less frequently recommended (13.5%) (fig. 3).

For high-risk young patients, breast ultrasound (89.4%) and self-examination (81.7%) were preferred, with only 39.4% recommending mammography. Screening frequency for moderate-risk women was predominantly every three years (53.8%), followed by every two years (31.7%).

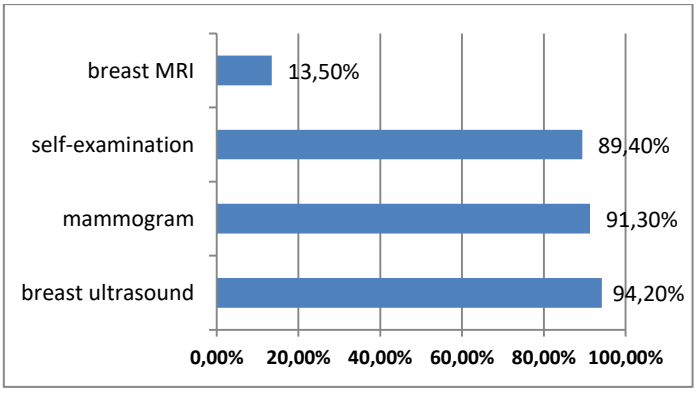

Fig. 3. Recommended types of screening

Challenges in patient monitoring and reimbursement

Among specialists, 76.9% were familiar with reimbursement procedures for breast cancer care. The most common barriers were delays in processing (38.5%), unclear procedures (33.3%), and additional administrative challenges (35.9%). Issues in re-

imbursement were reported as rare by 60.5% of respondents.

Challenges in patient monitoring included patient non-compliance (43.6%), limited access to imaging investigations (41%), and insufficient resources (38.5%). (fig. 4)

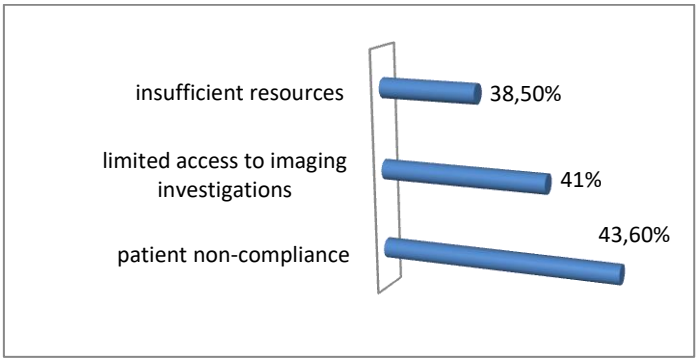

Fig. 4. Challenges in monitoring

Collaboration between specialists and family physicians

Collaboration with family physicians was rated as poor by 43.6% of specialists, while 28.2% considered it acceptable. Proposed improvements included interdisciplinary scientific meetings, training sessions, information bulletins, streamlined referral processes, and enhanced communication channels.

To assess the statistical significance of these differences, several tests were applied. The F-test confirmed significant variance differences between the two groups, justifying the use of a heteroscedastic t-test, which showed statistically significant differences in diagnostic preferences, reimbursement familiarity, and preventive measures. The Pearson correlation coefficient indicated a strong correlation (0.79) between gender and diagnostic recommendations, and a very high correlation (0.92) between mammo-graphy and ultrasound preferences. Conversely, a negative correlation (-0.50) was observed in certain diagnostic choices, indicating contrasting preferences between groups. Cancer frequency perception showed a moderate correlation (0.30) with professional background, while responses within each group were highly consistent (0.99 correlation). Familiarity with reimbursement procedures exhibited a perfect correlation (1.00), demonstrating uniform agreement. A strong correlation (0.95) was found between general practitioners' and specialists' views on prevention, although some prevention strategies showed a negative correlation (-0.38). Professional resource preferences were highly correlated (0.99), with some choices negatively associated with alternative decision-making factors (-0.78). Correlation curves were plotted to visualize these relationships, reinforcing statistical findings.

The correlation coefficient (0.954109) confirms a very strong linear relationship between the two variables, meaning that the responses or recommendations of specialists are highly consistent across the dataset (fig. 5).

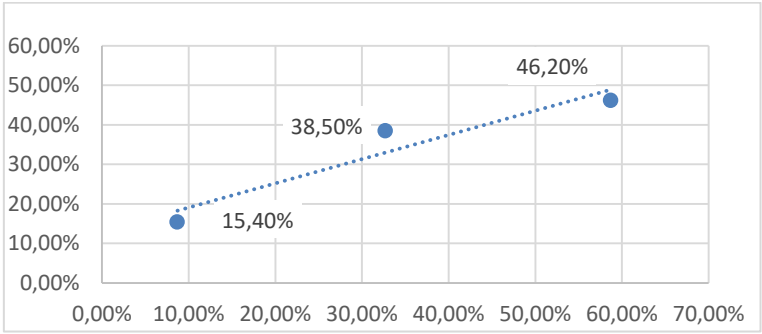

Fig. 5. Correlation between general practitioners' and specialists' views on prevention

DISCUSSION

The results of the questionnaire highlight several critical aspects that influence the management of breast cancer in Romania. One of the main findings is that while there is generally good knowledge of current diagnostic and treatment protocols, there are significant challenges related to collaboration between specialists and family physicians (7, 10, 11, 12-14). This lack of coordination can delay early diagnosis and optimal treatment strategies, which are essential for improving patient outcomes. Establishing a national database for rapid access to imaging investigations, strengthening prevention and screening programs, and reducing the turnaround time for pathological results are key steps that could improve breast cancer management (15-18).

Furthermore, there is a clear need to enhance education and awareness not only among healthcare professionals but also among patients, particularly young women and family physicians (19-22). Improving screening and patient management should involve national information campaigns, better access to diagnostic tests, greater involvement of family physicians in performing breast ultrasounds, and the deployment of mobile medical units in rural areas (23-27). Increasing funding for diagnostic tests, enhancing communication between healthcare providers, and implementing health education programs in schools are also necessary steps to ensure better early detection and treatment adherence.

A major concern identified in the study is the difficulty in reimbursing services and monitoring patients. The complexity of reimbursement procedures and bureaucratic delays further hinder access to timely diagnostics and treatment (16, 18, 28). Establishing a streamlined reimbursement system, along with integrating digital solutions for patient tracking, could alleviate some of these barriers.

Current research and increased awareness are essential to fully understand and respond to evolving trends in breast cancer incidence and patient characteristics. Globally, 90% of observed countries manage breast cancer diagnosis and treatment through multidisciplinary teams that adhere to national guidelines (11). Most European countries align their breast cancer care services with international standards, particularly those established by the European Society for Medical Oncology (12-14). However, Romania remains an exception, with significant gaps in service accessibil-

ity and financing. For example, genetic testing is not widely covered by public healthcare funds, despite its recognized importance in high-risk populations (29).

Survival rates vary significantly depending on the stage at diagnosis, with five-year survival rates ranging from 98% in early-stage diagnoses to only 24% in advanced-stage cases (19). In high-income countries, breast cancer mortality rates have been declining due to advancements in treatment and the widespread implementation of early screening programs. Unfortunately, Romania has one of the lowest participation rates in mammographic screening across the EU, with only 9% of eligible women being screened in 2020, compared to the EU average of 60% (20). A study conducted in Romania demonstrated that education plays a crucial role in influencing women's attitudes toward screening. However, national efforts to raise awareness and implement free breast cancer screening programs have been insufficient (21).

A critical issue remains the lack of studies examining the impact of social media campaigns on public awareness regarding screening importance and the benefits of early diagnosis. Research has shown that social media platforms such as Facebook, Twitter, and YouTube can significantly increase engagement and awareness regarding health-related topics (30). Utilizing targeted digital campaigns to educate younger women on self-examination and early detection strategies may help bridge existing knowledge gaps.

Another significant aspect of breast cancer care is psychological support. Emotional well-being plays a crucial role in patient satisfaction and treatment adherence. Patient advocacy groups and support networks have been shown to provide essential resources for breast cancer survivors, improving their quality of life. In addition, fostering supportive communities and increasing access to mental health services for patients undergoing treatment could enhance overall care standards (31).

To further optimize breast cancer management, Romania must align with European best practices, particularly regarding screening policies. The European Commission's Initiative on Breast Cancer (ECIBC) recommends organized population-based screening programs with biennial mammographic screening for women aged 50 to 69 (26). Additionally, improving national healthcare coverage and implementing more effective strategies for early detection are necessary to enhance survival rates. A systematic review of screening implementation strategies across Europe suggests that access to services, financial incentives, and primary care integration significantly impact participation rates (27).

In conclusion, the study highlights the urgent need to improve interdisciplinary collaboration, streamline reimbursement systems, and enhance patient education. A multifaceted approach-including policy reforms, public awareness campaigns, and greater investments in screening infrastructure-is essential for improving breast cancer outcomes in Romania. Further studies should focus on assessing the long-term impact of targeted interventions on screening adherence and patient survival rates.

CONCLUSIONS

This study highlights significant gaps in breast cancer prevention, screening, and treatment strategies in Romania. While specialists demonstrate substantial expertise, general practitioners face challenges in

accessing ongoing education and navigating referral pathways (19). Improved interdisciplinary collaboration, combined with essential policy reforms, could significantly enhance patient outcomes and reduce mortality rates.

A comprehensive approach that includes increased public awareness, standardized screening initiatives, and systematic healthcare system improvements is crucial to bridging existing gaps and ensuring efficient and timely breast cancer management in Romania (20).

Further research is required to assess the long-term impact of targeted interventions on breast cancer detection and treatment outcomes in Romania.

EVALUATION OF NEUROLOGIC EFFECTS OF SOME NEW IBUPROFEN THIAZOLIDIN-4-ONE DERIVATIVES (Abstract). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, are widely used to treat pain and inflammation associated with various conditions, including neurodegenerative diseases. The aim of this study was to evaluate the neurological effects of several new ibuprofen derivatives containing a thiazolidin-4-one moiety. **Materials and methods.** The effects of ibuprofen-thiazolidine-4-one derivatives (4a-n) on neuromotor function and locomotor activity in mice were assessed using the Rotarod and locomotor activity tests. The compounds were administered orally by gavage, as a suspension in tween 80, at a single daily dose equivalent to 1/20 of the LD50. A reference group, which received ibuprofen, and a control group, which received tween 80, were also used. **Results:** The ibuprofen-thiazolidine-4-one derivatives (4a-n) did not produce statistically significant changes in neuromotor performance, at any of the three time points assessed (1 hour, 2 hours, 6 hours post-administration). However, a significant decrease in total locomotor activity-both horizontal and vertical movements—was observed with compound 4b. Notably, several derivatives also led to a marked reduction in vertical movements. **Conclusions:** The observed decrease in vertical movements for some ibuprofen thiazolidine-4-one derivatives may indicate a potential anxiolytic effect, though this hypothesis requires validation through further studies. **Keywords:** IBUPROFEN, THIAZOLIDIN-4-ONE, LOCOMOTOR ACTIVITY, NEURO-LOGIC EFFECTS.

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) is a known class of therapeutics that relieve the inflammation and pain in various diseases as osteoarthritis, rheumatoid arthritis, renal colic, biliary colic, headache, dysmenorrhea and neurodegenerative diseases (1). Ibuprofen (an aryl propionic acid derivative) is a widely prescribed NSAID drug which, besides its known anti-inflammatory, analgesic and antipyretic effects, has some side effects such as gastro-intestinal, hepatic, renal or cardio-vascular toxicity (2). These disadvantages have led to the development of new candidates with a better pharmacotoxicological profile, such as thiazolidin-4-one derivatives.

Thiazolidin-4-one derivatives are heter-

ocyclic compounds with various biological effects such as antioxidant, anti-inflammatory, analgesic, antimicrobial or antitumoral (1, 3, 4). Using different methods to evaluate locomotor deficits in memory tasks, some studies evidenced their promising potential against oxidative damage and alterations in the cerebral area (5, 6). Some thiazolidin-4-one derivatives showed beneficial effects in the treatment of neurological diseases associated with neuroinflammation that indirectly support motor function recovery (4, 7).

Also, some clinical trials, have been developed to evaluate the therapeutic potential of NSAIDs, including ibuprofen in neurodegenerative diseases, knowing their promising neuroprotective effects (1, 8). The aim of the study was focused on evaluation of neurologic effects of new ibuprofen derivatives with thiazolidine-4-one structure (**4a-n)**, using two *in vivo* methods: rotarod and locomotor activity assays.

MATERIALS AND METHODS

Ibuprofen thiazolidin-4-one derivatives (**4a-n**) (fig. 1) were synthesized by our research group (3).

4f: R=3-NO_2 4m: R=4-NH_2
4g: R=4-NO_2 4n: R=4-$NHCOCH_3$

Fig. 1. Ibuprofen thiazolidin-4-one derivatives (**4a-n**).

The experiments were performed using Swiss albino mice provided from "Cantacuzino" Institute (Bucharest, Romania). The animals were kept in polyethylene cages with access to water and food ad libitum. The environmental conditions during the study were maintained relatively constant at a 20 ± 4°C temperature, 40-60% relative humidity and a 12 hrs. light/dark cycle. The food and the water were stop 18 hrs. before starting the experiments. The study was approved by the Ethical Committee of "Grigore T. Popa" University of Medicine and Pharmacy of Iasi (approval no. 292). All procedures were carried out in compliance with the European Community Guidelines (Directive 2010/63/EU) and Romanian law (Low no. 43/2014) on the protection of animals used for scientific purposes (1, 9). At the end of the study, all animals were euthanized in accordance with the legislation.

1. Rota-rod performance test

The Rota-rod test is very useful to evaluate the effect of new compounds on neuromotor performance, mainly, on brain function. This test is performed using the Rota-rod apparatus (Ugo Basile, Italy). With the help of five dividers and a revolving cylinder (rod), the device creates four lanes, each of which can hold one animal. A metal plate with a magnet affixed beneath each lane allows the resistance time to be recorded by stopping the timer when

the animal falls (10). The rod speed can be adjusted from the control panel, which features a digital display. According to the experimental protocol, animals were trained on the rotating rod at a speed of 15 rpm, and only those that remained on the rod for more than 60 seconds were selected. The apparatus recorded the time (in seconds) that each animal remained on the rod without falling, with a maximum allowed duration of 180 seconds (11,12). After training, the animals were divided into groups of eight, each receiving the test compounds (4a-n, L1-14), previously synthesized by our research group (3,9). The compounds were administered as a suspension in tween 80, orally by gavage, in a single daily dose of 1/20 of the LD50. To ensure accurate result interpretation, the study included a reference group, which received ibuprofen (L15), and a control group (L16), which received tween 80, used for administration of the tested compounds. The groups structure and administered doses (1/20 of LD50) are presented in first table.

TABLE I.

The groups and administered doses (mg/kg b.w.)

Group	Compound	Doses (mg/ kg b.w.)	Group	Compound	Dose (mg/ kg b.w.)
L1	**4a**	81.25	**L9**	**4i**	86.00
L2	**4b**	81.25	**L10**	**4j**	92.00
L3	**4c**	86.40	**L11**	**4k**	78.25
L4	**4d**	81.70	**L12**	**4l**	79.50
L5	**4e**	91.00	**L13**	**4m**	82.50
L6	**4f**	89.50	**L14**	**4n**	85.00
L7	**4g**	91.00	**L15**	**Ibuprofen**	68.75
L8	**4h**	89.50	**L16/Control**	**Tween 80**	0.1 mL/10 g

At 1 hour, 2 hours, and 4 hours after administration, the mice were subjected again to the test, and the time that the mice remained on the rotating rod was recorded each time. The initial time value, in seconds, was calculated as the arithmetic mean of the values at which all mice remained on the rotating rod at time zero (before the administration of the tested compounds) ± standard deviation.

2. Locomotor activity test

The effect of the tested compounds (4a-n) on spontaneous locomotor activity was analyzed using the IR Actimeter LE-8811 (Panlab, Spain). This device consists of a cage with dimensions of 45 cm (width) × 45 cm (length) × 20 cm (height), equipped with a control unit. The cage is fitted with an infrared frame system that allows monitoring of both vertical and horizontal movements, with multiple sensitivity levels that can be adjusted depending on the animal used. This frame is connected via the control unit to the SeDaCom computer program, which converts recorded data into Notepad formats. During the experiment, three cages were used.

According to the experimental protocol, the animals were divided into several groups (Table I), each consisting of eight mice, and then placed in the cages (one animal per cage). Their horizontal and

vertical movements were recorded for 5 minutes. After this time, the tested compounds were administered orally as a suspension in tween 80, at a dose of 1/20 of the LD50. Measurements were repeated at 1 hour, 2 hours, and 4 hours after administration, with the mice being placed back into the same cage each time. For each tested compound, as well as for the reference group (ibuprofen) and the control group (tween 80), total locomotor activity was determined, representing the total number of electronically recorded movements in both horizontal and vertical planes.

The initial values for horizontal and vertical movements, as well as the total value, were calculated as the arithmetic mean of all the animals studied at time zero (before the administration) ± standard deviation.

The one-way analysis of variance (ANOVA) and T-test were used to determine whether there are any statistically significant differences between tested compounds and controls. The p value < 0.05 was considered to be statistically significant.

RESULTS

1. Rota-rod performance test

The Rota-rod test evaluates the motor coordination of the animals, before and after the administration of tested compounds. For each group were calculated the latency, respectively the time expressed in seconds of how long did the animals lasted on the Rota-rod without falling. The obtained results are presented in the second table.

This test can provide data on motor coordination as well as other aspects of neuromotor function, such as motor learning, which is demonstrated by improved performance after successive trials (13).

TABLE II.

Time (seconds) recorded for animals treated with tested compounds

Group	Time (sec)		
	1 hr.	2 hrs.	4 hrs.
L1	164.29±29.36	162.14±29.70	160.29±25.57
L2	166.50±33.07	165.50±23.81	164.00±25.92
L3	167.60±21.65	164.83±28.15	161.67±27.14
L4	166.50±18.32	165.33±25.41	163.83±27.64
L5	167.67±30.21	166.67±31.21	165.33±30.85
L6	166.80±29.52	166.00±31.30	164.00±20.74
L7	167.00±29.07	166.00±21.91	159.00±25.90
L8	165.17±23.46	164.50±27.60	163.17±28.42
L9	167.00±20.93	165.33±24.39	164.83±28.00
L10	166.83±23.84	165.00±26.77	163.00±28.45
L11	167.33±27.30	164.67±23.89	164.17±24.58
L12	167.83±21.53	166.67±19.66	165.83±18.05
L13	166.67±13.42	165.33±25.55	164.50±25.88
L14	167.50±24.03	166.50±28.45	164.67±28.89
L15	165.80±31.75	156.86±27.22	153.50±30.49
L16	166.33±28.86	165.00±28.11	164.17±30.07
INITIAL	167.20±24.02		

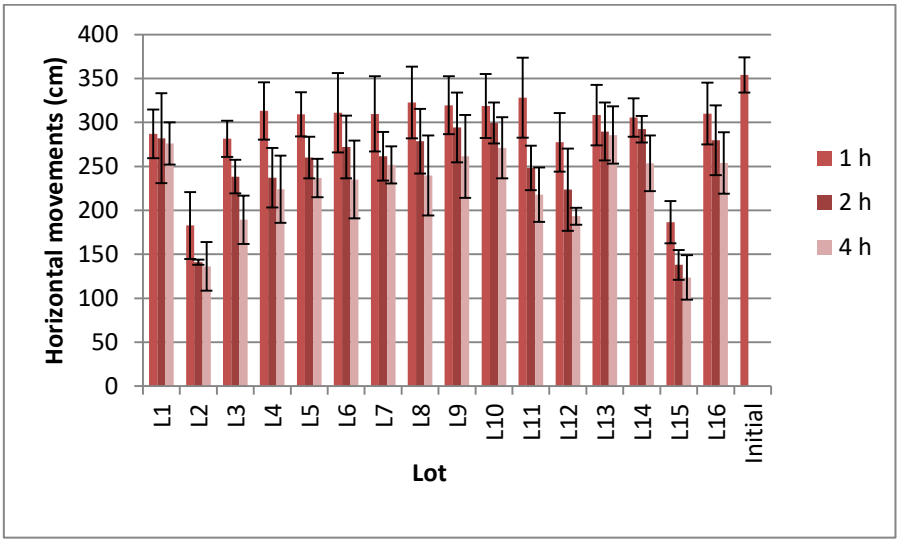
From the analysis of obtained results was noticed that groups treated with tested compounds (L1-L14), ibuprofen (L15) and vehicle (L16) did not display statistically significant differences ($p>0.05$), in all three intervals of time (1 hour, 2 hours, 6 hours). At the same time there were not registered statistically significant differences towards the initial value, before the administration of tested compounds. These observations led to the conclusion that ibuprofen as well as the studied derivatives of ibuprofen with thiazolidine-4-one structure had no influence on motility of the mice, respectively on motor coordination. Also, Singh *et al.* remarked that ibuprofen did not modify the grip strength, distance travelled and time spent on Rota-rod apparatus (14).

Locomotor activity test

It is known that the locomotor activity assay is a behavioral test and is easily influenced by study conditions such as light, cage dimensions or habituation with this space. This test is often used for pharmacological evaluation of new compounds that could be potential therapeutic agents (15). By using this behavioral test, important information relating to spontaneous locomotor activity in experimental animals, in both horizontal and vertical sides, as well as to total locomotor activity, were obtained.

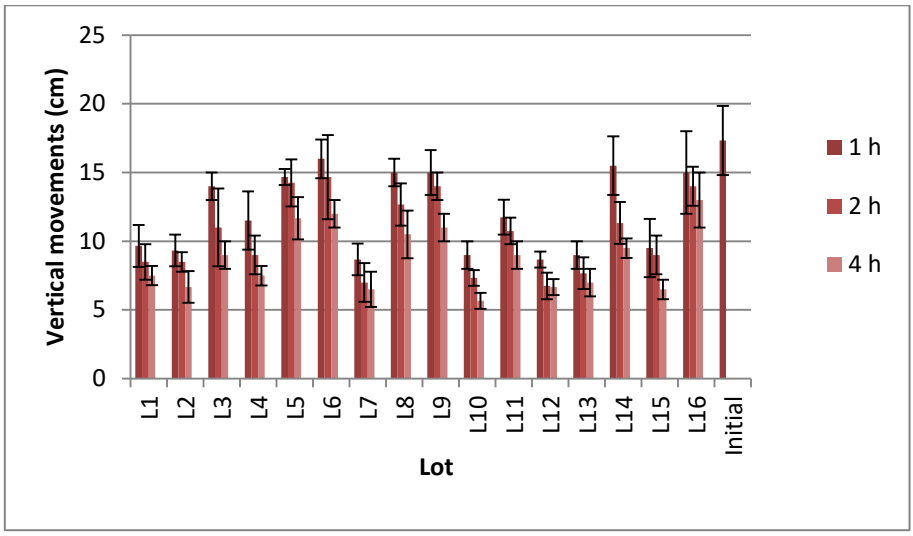
Horizontal movements can provide information relating to the animal's exploration behavior, but also to that of attending to its own hygiene (paw licking, hair and nose cleaning). Vertical movements characterized by the animal's climbing attempt, on the cage's transparent walls can indirectly indicate the animal's fear or anxiety (12).

The obtained results are presented in figures 2-4.



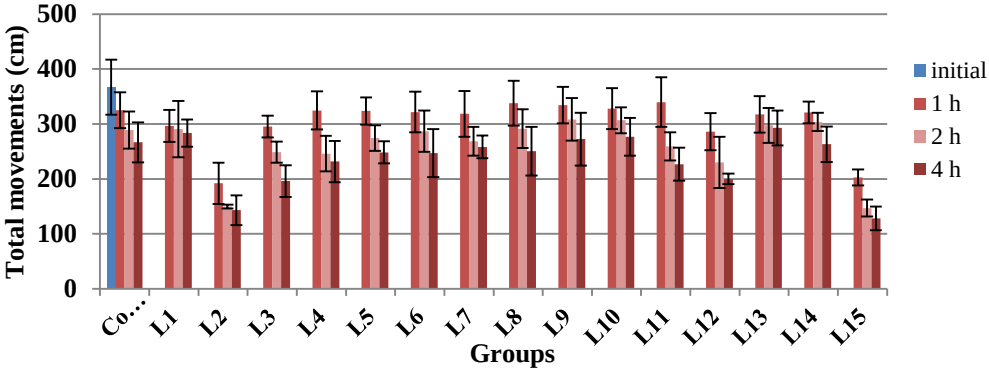
* data represents the average of 8 values ± standard deviation

Fig. 2. Locomotor activity registered in horizontal side of experimental animals treated with studied compounds in comparison with ibuprofen (L15)



* data represents the average of 8 values ± standard deviation

Fig. 3. Locomotor activity registered in vertical side of experimental animals treated with studied compounds in comparison with ibuprofen (L15).



* data represents the average of 8 values ± standard deviation

Fig. 4. Total locomotor activity registered to experimental animals treated with studied compounds in comparison with ibuprofen (L15).

DISCUSSION

Relating to locomotor activity in horizontal side, a significant decreasing of the movements number was noticed in groups treated with ibuprofen (p = 0.006, L15) and **4b** compound (p = 0.004, L2). It seems that the substitution of phenyl ring with chloro may influence the locomotor activity.

The analysis of the locomotor activity registered in vertical side pointed out a statistically significant decline for ibuprofen (p = 0.006) and **4b** compound (p = 0.004) as well as for following derivatives: **4a** (p = 0.003, R = H, L1), **4d** (p = 0.023, R = 4-F, L4), **4g** (p = 0.001, R = 4-NO2, L7), **4j** (p = 0.004, R = 4-CF3, L10), **4k** (p = 0.024, R = 4-CN, L11), **4l**

(p = 0.001, R = 2,6-dichloro, L12) and **4m** (p = 0.001, R= 4-NH2, L13).

From the total locomotor activity point of view, at different time intervals (1 hour, 2 hours, 4 hours), was noticed that the majority of groups did not display statistically significant differences (p>0.05) in comparison to the control group.

A significant reduction in the total numbers of movements (in horizontal and vertical sides) was registered only in groups that were treated with ibuprofen (p = 0.008, L15) and with **4b** derivative (2-(4-chlorophenyl)-3-[2-(4-isobutylphenyl)-2-methyl]acetamide-thiazolidine-4-one, p = 0.004, L2).

Lee *et al*. have been evaluated the effect of ibuprofen in induced stress model with anxiety induced to rats.

Open-field activity was used to evaluate locomotion and exploratory behavior and even if the results were not statistically significant it was observed a decrease in the numbers of crossing in the central zone (16). Another study included salicylic acid and its prodrug that presented some potential of decreasing neuro-inflammation in mice. In the behavioral studies such as open field test, it was evidenced some reduced locomotor activity (9).

CONCLUSIONS

New ibuprofen derivatives with thiazolidine-4-one structure were tested from the point of view of motor coordination (through Rota-rod test) and of spontaneous locomotor activity (behavioral test). The obtained results during the Rota-rod test support the observation that studied derivatives do not influence significantly the experimental animal's motor coordination. At the same time the registered effect for these compounds on the locomotor function was similar to the one observed in case of ibuprofen.

In behavioral tests, derivative **4b** (2-(4-chlorophenyl)-3-[2-(4-isobutylphenyl)-2-methyl] acetamido-thiazolidin-4-one) reduced the total locomotor activity and horizontal movements, exhibiting effects similar to those induced by ibuprofen. The observed decrease in vertical movements for certain derivatives may suggest an anxiolytic effect, though this hypothesis requires validation through further studies.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest.

FUNDING

FINITE ELEMENT ANALYSIS OF THE EFFECT OF INSERTION ANGLE AND DIAMETER ON STRESS, STRAIN, AND DISPLACEMENT IN ORTHODONTIC MINI-IMPLANTS (Abstract): Orthodontic mini-implants are widely used as temporary anchorage devices, and their clinical performance depends on biomechanical factors related to implant design and insertion technique. **Materials and methods**: A three-dimensional finite element model of an orthodontic mini-implant inserted into cortical and cancellous bone was developed. Three insertion angles relative to the cortical bone surface (60°, 90°, and 120°) and two mini-implant diameters (1.5 mm and 2.0 mm) were analyzed under standardized orthodontic loading conditions. Total displacement, equivalent von Mises stress, and equivalent linear strain were evaluated. **Results:** Higher insertion angles resulted in increased displacement and strain, with the highest values observed at 120°. Maximum von Mises stress values were comparable among different angles; however, stress distribution patterns and stress localization varied significantly. Mini-implants with a smaller diameter exhibited higher displacement and stress values, indicating reduced mechanical stiffness, while larger-diameter mini-implants demonstrated improved biomechanical performance. **Conclusions:** Both insertion angle and mini-implant diameter significantly influence the mechanical behavior of orthodontic mini-implants. Perpendicular insertion and increased implant diameter were associated with reduced deformation and more favorable stress distribution, suggesting improved primary stability and clinical performance. **Keywords**: FINITE ELEMENT ANALYSIS; ORTHODONTIC MINI-IMPLANTS; INSERTION ANGLE; IMPLANT DIAMETER; BIOMECHANICS.

INTRODUCTION

Orthodontic mini-implants, also referred to as Temporary Anchorage Devices (TADs), have gained significant traction in contemporary orthodontic treatments. The mechanical behavior of these implants is significantly influenced by geometric parameters such as insertion angle and diameter. Understanding these influences is crucial for optimizing the design and application of mini-implants in clinical settings.

TADs demonstrate variable success rates, with studies indicating that failure rates typically range from 9% to 30% (1). Various systematic reviews have reported success rates for TADs from 80% to 94% (2, 3). The relatively high reliability of mini-implants can largely be attributed to their design, which enables stable anchorage even under orthodontic loading conditions, cru-

cial for effective tooth movement (4, 5).

The insertion of mini-implants is a minimally invasive procedure compared to traditional orthodontic anchorage methods, such as palatally installed implants or miniplates (6). The ability to insert these devices without the need for extensive surgical interventions enhances patient comfort and expedites the treatment process (7, 8).

Research has indicated that mini-implants can significantly broaden the range of treatment strategies available to orthodontists. For example, they have been effectively utilized in complex cases, such as maxillary protraction and closure of extraction spaces, allowing for more efficient treatment sequences (9, 10). Their versatility makes them suitable for various applications, including en-masse retraction and space closure procedures (11, 12).

Ongoing research is focused on improving the design and stability of mini-implants. Studies have explored surface modifications to enhance osseointegration and stability (13), and new findings on optimal insertion protocols continue to emerge (14). The stability of mini-implants, both during the healing phase and after mechanical loading, has been a primary focus, with findings suggesting that various lengths and diameters can impact their success rates (15, 16).

While mini-implants present numerous advantages, they are not without risks. Factors that may influence the failure of mini-implants include patient age, oral hygiene, the placement site's bone density, and the amount of force applied during orthodontic treatment (3, 16). Thus, careful patient selection and technique adjustments are crucial for optimizing their performance (5).

The interplay between insertion angle and diameter further complicates the mechanical behavior of orthodontic mini-implants. Wu *et al*. explored how design variables, including taper shape and diameter, jointly influence mechanical stability (17). They found that specific combinations of insertion angle and diameter could lead to optimized outcomes in terms of anchorage strength and resistance to mechanical loading.

FEA is favored in biomechanical studies of orthodontic mini-implants due to its ability to model complex structures and simulate physiological responses accurately. The application of FEA allows researchers to predict stress distribution patterns around mini-implants under different forces, thus facilitating the design of implants that can withstand significant loading without failure (18, 19). By employing FEA, orthodontists can assess the mechanical performance of mini-implants, unveiling insights about their interactions with surrounding bone and tissues that would be difficult to quantify through traditional *in-vivo* experiments (20, 21).

The aim of this study was to evaluate, using finite element analysis (FEA), the influence of insertion angle and diameter on the biomechanical behavior of orthodontic mini-implants. Specifically, the study investigated the effects of three insertion angles (60°, 90°, and 120° relative to the cortical bone surface) and two mini-implant diameters (1.5 mm and 2.0 mm) on total displacement, equivalent von Mises stress, and equivalent strain distributions within the mini-implant.

The objective of this analysis was to identify biomechanically favorable insertion configurations that minimize displacement and stress concentration, thereby contributing to improved primary stability

and providing biomechanical support for clinical decision-making regarding orthodontic mini-implant placement.

MATERIALS AND METHODS

A three-dimensional finite element analysis (FEA) was performed to evaluate the biomechanical behavior of orthodontic mini-implants under different insertion angles and diameters. The modeling process consisted of geometric modeling, material property assignment, mesh generation, application of boundary conditions and loads, and result analysis.

Geometric Modeling. The mandibular model, including teeth and periodontal ligament (PDL), was reconstructed from computed tomography (CT) images, which were digitized and converted into three-dimensional solid models. The periodontal ligament was modeled with a uniform thickness of 0.25 mm based on the external geometry of the tooth roots. Commercially inspired mini-implant models were created according to Leone® and Dual Top Jeil Medical Corporation® (Seoul, Korea) designs.

Two mini-implant diameters (1.5 mm and 2.0 mm) and a total length of 12 mm with a maximum insertion depth of 9 mm were analyzed. Mini-implants were virtually inserted at depths of 5, 6, and 7 mm into cortical and cancellous bone. The insertion site was defined as the interradicular space between the premolar and molar region.

All geometric models were created and assembled using SpaceClaim (ANSYS Inc., USA).

Finite Element Model

The assembled models were imported into ANSYS Workbench (version 2021, ANSYS Inc., USA) and discretized using three-dimensional 10-node tetrahedral elements. A mesh convergence study was performed with element sizes ranging from 0.3 mm to 1.2 mm. An element size of 0.3 mm was selected in the mini-implant insertion region, while a size of 0.8 mm was used for the remaining volume.

All materials (bone, teeth, PDL, and mini-implants) were assumed to be linear elastic, homogeneous, and isotropic. Material properties were assigned based on values reported in the literature. Mini-implants were modeled using Ti-6Al-4V alloy for Dual Top Jeil Medical Corporation® implants and stainless steel 316L for Leone® implants.

Contact Conditions and Boundary Condition. The interfaces between teeth and periodontal ligament were assumed to be perfectly bonded. A frictionless contact (coefficient of friction = 0) was defined between the mini-implant and bone. The proximal and distal surfaces of the mandibular bone were fixed in all directions to simulate boundary constraints.

Loading Conditions. Orthodontic forces ranging from 0.1 N to 10 N were considered. A force magnitude of 2 N, corresponding to the upper limit of clinically accepted immediate loading, was applied to the head of the mini-implant. The force was oriented obliquely in the proximal direction to simulate en-masse tooth retraction and to allow comparative analysis between different insertion angles and implant diameters.

Outcome Measures. The numerical simulations evaluated total displacement, equivalent von Mises stress, and equivalent linear strain distributions within the mini-implant and surrounding bone structures. The results were analyzed to assess the influence of insertion angle and implant diameter on the biomechanical behavior of

orthodontic mini-implants.

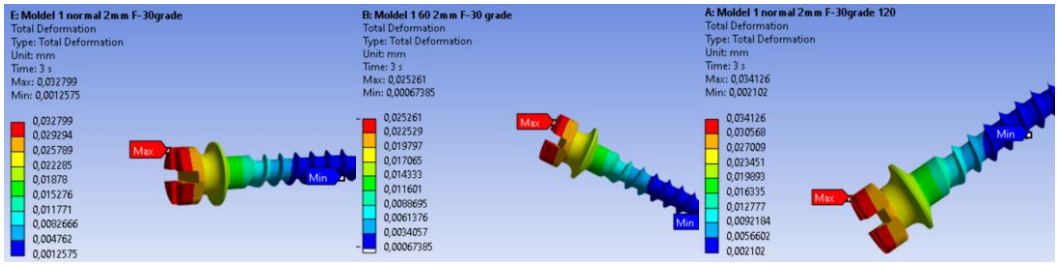
RESULTS

Influence of the mini-implant inclination angle relative to the Y-axis

Total displacements

The total deformation state of the mini-implant as a function of the inclination angle relative to the cortical bone surface is presented in first figure. Higher values are obtained for an inclination angle of 120°. The results indicate that the inclination angle significantly influences the displacement state.

The comparative values of the maximum total displacements in the mini-implant as a function of the inclination angle relative to the cortical bone surface are presented in figure 2.



90º 60º 120º

Fig. 1. Total deformation state of the mini-implant as a function of the inclination angle relative to the cortical bone surface.

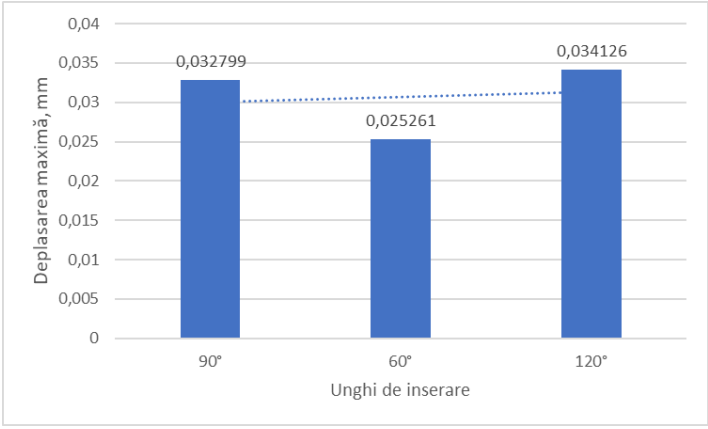


Fig. 2. Comparative values of the maximum total displacements in the mini-implant as a function of the inclination angle relative to the cortical bone surface.

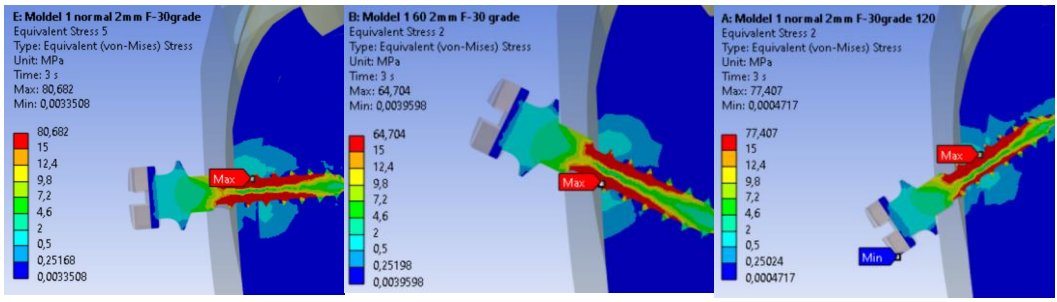
Equivalent von Mises stresses

The stress distribution for the three inclination angles relative to the cortical bone surface, shown in cross-section, is presented in figure 3. The maximum value obtained is 138.92 MPa for the case of an insertion length of 5 mm into the bone. The maximum values for the three analyzed cases are relatively close. The results indicate that the stress distribution pattern differs significantly among the analyzed cases, with the maximum stress

located at a shallower depth for the 60° inclination.

The comparative values of the maximum stress as a function of the inclination angle relative to the cortical bone surface are presented in fourth figure.



90º 60º 120º

Fig. 3. Stress distribution for the three inclination angles relative to the cortical bone surface, shown in cross-section.

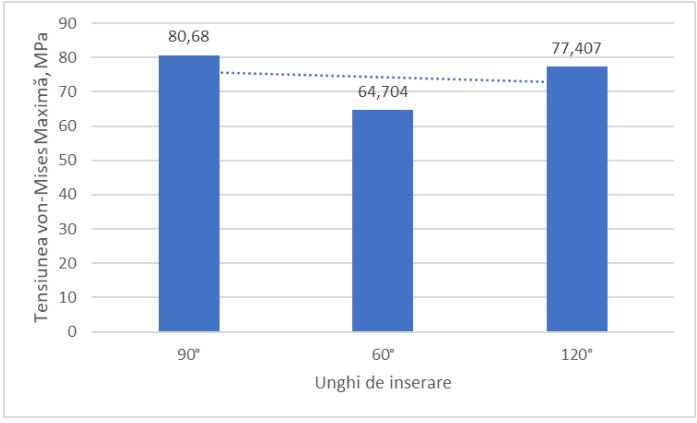


Fig. 4. Comparative values of the maximum stress as a function of the inclination angle relative to the cortical bone surface.

Equivalent strains

The equivalent linear strain distribution for the three inclination angles relative to the cortical bone surface is presented in figure 5. The maximum value obtained is 0.009677 mm/mm for the inclination angle of 120°. The volume of stressed material is greater for the 60° and 120° cases compared to the 90° case.

The comparative values of the equivalent strains as a function of the inclination angle relative to the cortical bone surface are presented in figure 6

Influence of the mini-implant Diameter. Total displacements

The total deformation state of the mini-implant as a function of the mini-implant type is presented in Fig. 7, with the mini-implant of 1.5 mm diameter shown on the left and the 2 mm diameter mini-implant shown on the right. Higher values are obtained for the

smaller-diameter implant. The results indicate that the diameter significantly influences the displacement state, which is physically consistent, as the bending moment of inertia for a circular cross-section increases with diameter, resulting in a stiffer system.

Model 1 d = 1,5 mm Model 2 d = 2 mm

Fig. 7. Total deformation state of the mini-implant as a function of the mini-implant type.

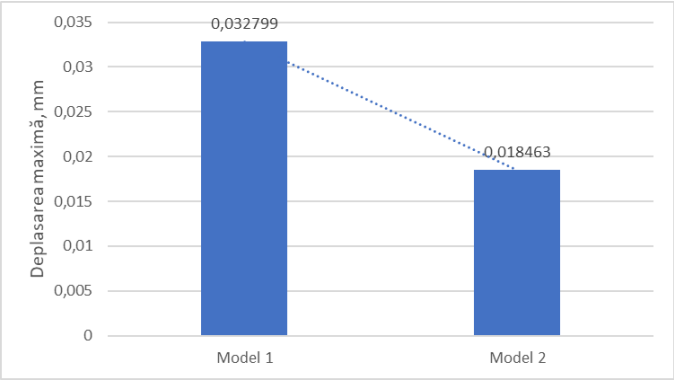

Fig. 8. Comparative values of the maximum total displacements in the mini-implant as a function of its type.

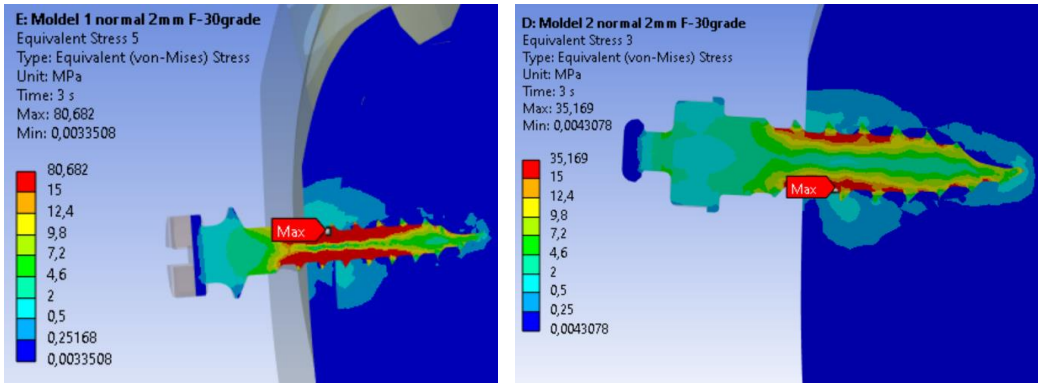
Equivalent von Mises stresses

The stress distribution for the different insertion lengths of the implant, shown in cross-section, is presented in Fig. 9 The maximum value obtained is 80.682 MPa for the model 1 mini-implant with a diameter of 1.5 mm, while the minimum value is 35.169 MPa for the model 2 mini-implant with a diameter of 2 mm. The results indicate that the stress distribution differs significantly between the two analyzed cases. It can also be observed that the volume of affected material is greater for the model 2 mini-implant.



Model 1 d = 1,5 mm Model 2 d = 2 mm

Fig. 9. Stress distribution for the different insertion lengths of the implant, shown in cross-section.

The comparative values of the maximum stress as a function of the mini-implant model are presented in figure10.

Equivalent strains

The equivalent linear strain distribution for the two mini-implant models is presented in figure 11. The maximum value obtained is 0.0066167 mm/mm for model 2. The results indicate that the distribution of equivalent strains differs between the two analyzed cases, with the maximum located

at different positions.

Figure 12 presents the comparative values of the equivalent strains as a function of the mini-implant type.

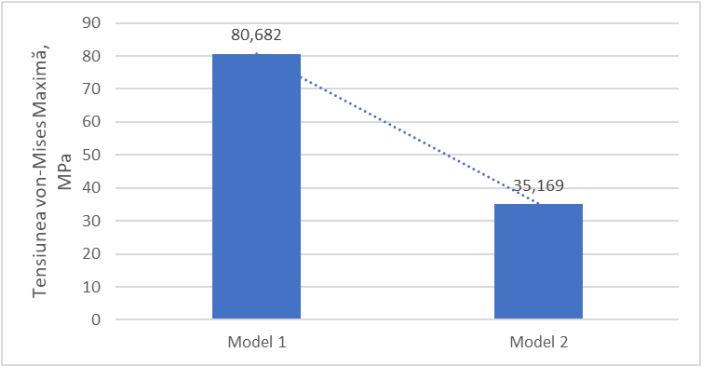


Fig. 10. Comparative values of the maximum stress as a function of the mini-implant model.

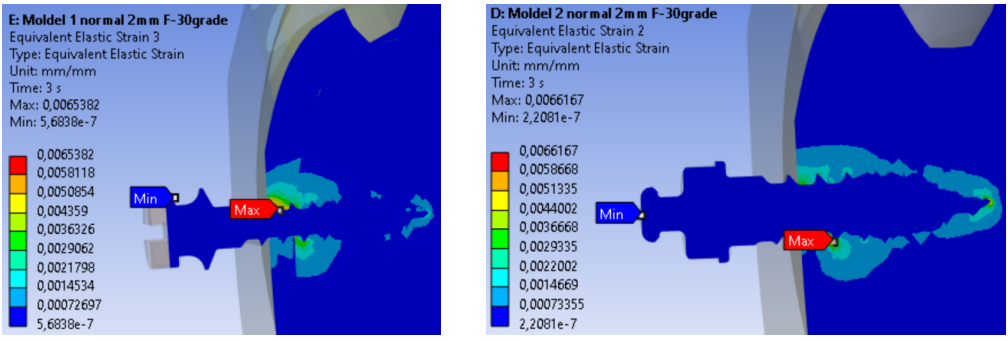

Model 1 d = 1,5 mm Model 2 d = 2 mm

Fig. 11. Equivalent linear strain distribution for the two mini-implant models.

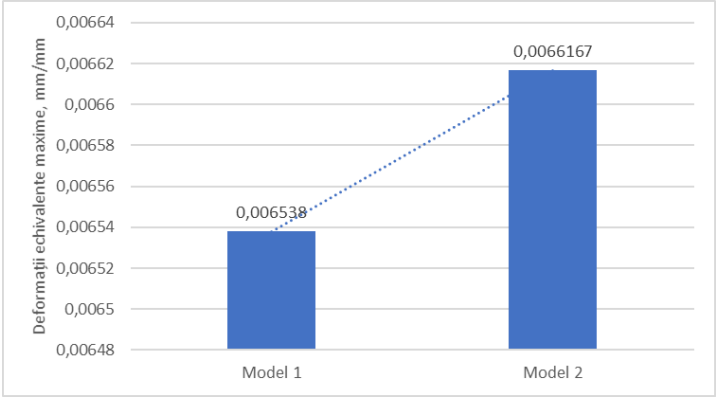

Fig. 12. Comparative values of the equivalent strains as a function of the mini-implant type.

DISCUSSION

Orthodontic mini-implants serve as pivotal anchorage devices in modern orthodontics, enabling effective treatment outcomes through strategic force application. The insertion angle of these implants significantly affects their displacement and overall stability. This article discusses the findings from various finite element studies regarding the impact of increased insertion angles, such as 120°, compared to perpendicular placements at 90° (TABLE 1).

Several studies establish a correlation between the angle of insertion and the displacement of orthodontic mini-implants. For example, a study by Motoyoshi *et al*. emphasizes that increased angles of insertion can lead to heightened stress on surrounding cortical bone, consequently increasing the displacement experienced by the implants (22). This claim is supported by the findings of Sana *et al*., who concluded that oblique angles can create longer lever arms, thereby impacting engagement between the implant threads and the bone (23).

Moreover, a finite element analysis (FEA) study conducted by Xavier *et al*. indicated that an increase in insertion angle from 90° to 45° resulted in greater strain and insertion torque, which was correlated to increased displacement (24).

TABLE I.

Influence of insertion angle on displacement: comparison between present study and literature

Parameter	Present FEM Study	Findings from Literature
Insertion angle	60°, 90°, 120°	45°-120° (22, 25)
Total displacement	Highest displacement observed at 120°; lowest at 90°	Increased displacement reported for oblique angles compared to perpendicular insertion (22, 23)
Mechanical explanation	Increased lever arm and reduced thread engagement at higher angles	Oblique insertion increases bending moments and reduces cortical bone engagement (23, 24)
Clinical implication	Higher angulation may compromise primary stability	Oblique insertion associated with increased risk of micromovement and instability (25)

The primary stability of mini-implants is critical for their success, and the insertion angle plays a vital role in this regard. Wilmes *et al*. report that the insertion angle significantly impacts the primary stability of these implants, with angular placements at 120° being more susceptible to movement than perpendicular placements (25).

A thorough understanding of stress distribution patterns surrounding mini-implants is necessary to evaluate their performance under different insertion angles (tables 2). Sivamurthy and Sundari's study highlights significant alterations in axial load reactions with varying insertion angles (26). The outcomes of this study align with those from Chaddad *et al*., which examined how surface characteristics, including angle of insertion, influence stress on the mini-

implant interface and subsequently affect displacement (27). The correlation between insertion angle and stress allows for deeper insights into how misalignment can increase the risk of failure in clinically modeled scenarios (28).

TABLE II.
Influence of insertion angle on stress distribution

Aspect	Present FEM Study	Literature Findings
Maximum von Mises stress	Similar peak stress values for all angles	Comparable peak stresses reported across angles (26)
Stress distribution	Significant variation in stress localization; shallower stress concentration at 60°	Stress concentration shifts With insertion angle (27, 28)
Risk of failure	Altered stress distribution may increase localized bone overload	Misalignment linked to higher failure risk due to uneven stress (28)

Study limitations

This finite element study is subject to certain limitations.

a. The finite element models assumed all materials (bone, teeth, periodontal ligament, and mini-implants) to be linear elastic, homogeneous, and isotropic, which does not fully reflect the complex anisotropic behavior of biological tissues in vivo.

b. A frictionless contact condition was defined at the bone-mini-implant interface, which may underestimate the effects of interfacial friction and mechanical interlocking occurring in clinical situations.

c. The geometry of the mandibular bone was simplified to reduce computational time, potentially affecting the accuracy of stress and strain distribution in anatomically complex regions.

d. Only static loading conditions were considered, whereas cyclic and dynamic orthodontic forces may influence long-term mini-implant stability.

e. Biological factors such as bone remodeling, osseointegration, and patient-specific variability were not included in the finite element simulations.

f. The study evaluated a limited range of insertion angles and implant diameters; therefore, the results may not be directly generalizable to all commercially available mini-implant designs.

g. The findings are based on numerical simulations and should be interpreted as comparative biomechanical trends rather than absolute predictors of clinical performance.

CONCLUSIONS

This finite element study demonstrated that both insertion angle and mini-implant diameter significantly affect the mechanical behavior of orthodontic mini-implants. Higher insertion angles increased displacement and strain, while larger diameters improved mechanical stability and stress distribution. These findings may support optimized clinical placement of orthodontic mini-implants.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

ATOMIC FORCE MICROSCOPY CHARACTERIZATION OF A THREE-DIMENSIONAL PORCINE COLLAGEN MATRIX FOR PERIODONTAL APPLICATIONS UNDER HYDRATED CONDITIONS (Abstract): The **aim** of this study was to characterize the nanoscale surface topography of a three-dimensional porcine collagen matrix under hydrated conditions, simulating a physiologically relevant environment. **Materials and methods:** Atomic force microscopy (AFM) was performed in hydrated conditions to evaluate surface topography, deflection signal, three-dimensional reconstruction, surface profile, and quantitative roughness parameters. **Results:** The collagen matrix exhibited a continuous, moderately undulating surface without detectable structural defects. Topographic analysis revealed a homogeneous distribution of elevations and depressions, consistent with an isotropic collagen network. Deflection imaging enhanced the visualization of local slope variations, indicating microstructural heterogeneity. Three-dimensional reconstruction confirmed uniform spatial organization with gradual height transitions. Quantitative analysis demonstrated moderate roughness (Sa = 0.1179 µm; Sq = 0.1765 µm) and limited maximum height (Sz = 1.541 µm), suggesting the absence of pronounced irregularities. Height distribution showed a centered dispersion around the mean plane. **Conclusions:** The hydrated collagen matrix presents a stable, continuous, and moderately rough surface morphology, which may support favorable biological interactions and its potential application in soft tissue and periodontal regeneration. **Keywords:** ATOMIC FORCE MICROSCOPY, COLLAGEN MATRIX, SURFACE TOPOGRAPHY, HYDRATED CONDITIONS, ROUGHNESS, BIOMATERIALS, PERIODONTAL REGENERATION, NANOSCALE MORPHOLOGY.

INTRODUCTION

Collagen-based biomaterials are widely used in regenerative dentistry and periodontology due to their biocompatibility, biodegradability, and structural similarity to the native extracellular matrix (1, 2). Porcine-derived collagen matrices, in particular, have been increasingly employed as substitutes for autogenous grafts in soft tissue augmentation procedures, offering advantages such as reduced morbidity and simplified surgical protocols (3, 4). The surface morphology of these biomaterials plays a critical role in their biological performance, influencing protein adsorption, cell adhesion, proliferation, and tissue integration (5, 6). At the micro- and nanoscale levels, surface topography has been shown

to modulate cellular behavior and affect the interaction between biomaterials and the surrounding biological environment (7).

Atomic force microscopy (AFM) is a powerful technique for nanoscale surface characterization, providing high-resolution topographical data and information regarding surface roughness and local mechanical interactions (8). Unlike other imaging methods, AFM allows the investigation of soft biomaterials under hydrated conditions, which more closely resemble physiological environments (9).

Hydration significantly affects the structural and mechanical properties of collagen-based materials, leading to changes in surface morphology, compliance, and topographical features (10). In hydrated conditions, collagen matrices may exhibit a more relaxed structural configuration, potentially reducing apparent surface roughness and altering the visualization of microstructural details (11). Despite the widespread clinical use of collagen matrices, limited data is available regarding their nanoscale surface characteristics under physiologically relevant conditions (12). Most existing studies focus on dry-state analysis, which may not accurately reflect vivo behavior.

Therefore, the aim of the present study was to characterize, using atomic force microscopy, the surface topography of a three-dimensional porcine collagen matrix under hydrated conditions, with particular emphasis on morphological features and rough surface parameters.

MATERIALS AND METHODS

Materials. A commercially available three-dimensional porcine collagen matrix, Mucoderm® (Botiss biomaterials GmbH Zossen-Germany), was used in this study. The material consists of a collagen-based structure designed for soft tissue applications. Prior to analysis, 30 samples were prepared according to standard handling protocols and maintained for 20 minutes in hydrated conditions (sterile NaCl 0.9% solution) according to the manufacturer recommendations. Hydration is an essential step in order to obtain an optimal oral integration in a clinical setting.

AFM images were acquired on synthetic tissue samples in a hydrated state to evaluate surface topography under conditions closely resembling the physiological environment. Hydration affects both the mechanical behavior and the morphological configuration of the surface, inducing structural relaxation of the collagen network and facilitating a more accurate representation of surface irregularities, depressions, and local topographical variations.

Sample Preparation. The specimens of appropriate dimensions (10 mm diameter) placed on a stable support suitable for AFM analysis. Measurements were performed in wet conditions, ensuring the presence of a hydration layer throughout the scanning process. This approach was selected to preserve the native structural configuration of the collagen matrix and to minimize artifacts associated with dehydration.

Atomic Force Microscopy Analysis. Atomic Force Microscopy (AFM) investigations were carried out using an EasyScan 2 system (Nanosurf AG, Liestal, Switzerland), equipped with a highly sensitive PPP-NCHAuD cantilever (NanoAndMore, USA), characterized by a resonance frequency of approximately 330 kHz, a spring constant of 44 N/m, and a length of 125

µm. Image acquisition was performed in Dynamic Force mode (Non-Contact Mode), while data processing was conducted using the dedicated Nanosurf EasyScan 2 analysis software. To ensure stable immobilization of the synthetic tissue and enhance measurement reproducibility, the samples were mounted on commercially available glass slides coated with poly-L-lysine (PLL), which promotes electrostatic adhesion of biological specimens. AFM scans were carried out under hydrated conditions, and prior to imaging, the substrates were allowed to reach thermal equilibrium with the scanning cell environment in order to minimize experimental variability.

The scans were performed over an area of 5 × 5 µm, allowing detailed visualization of surface morphology at the micro- and nanoscale. Several imaging channels were recorded, including: height (topography) images, deflection images, three-dimensional surface reconstructions

Surface Analysis. Topographic images were analyzed to evaluate the overall morphology and spatial distribution of surface features. Deflection images were used to enhance the visualization of local slope variations and microstructural boundaries.Three-dimensional reconstructions were generated to assess the spatial organization of the surface. Surface profiles were extracted along selected cross-sections to evaluate height variations.

Roughness Parameters. Surface roughness parameters were calculated from AFM data, including following parameters:Sa (arithmetical mean height),Sq (root mean square roughness), Sz (maximum height), Ssk (skewness), Sku (kurtosis).These parameters were used to quantify the amplitude and distribution of surface irregularities.

Statistical Representation. Height distribution histograms were generated to evaluate the distribution of surface elevations relative to the mean plane. This allowed the assessment of symmetry, dispersion, and the presence of extreme values within the dataset.

RESULTS

AFM Topography Analysis. AFM topography images acquired on the synthetic tissue in a hydrated state revealed a surface characterized by a non-uniform relief, dominated by heterogeneously distributed morphological variations. An alternation between slightly elevated regions and localized depressions was observed, suggesting a discontinuous spatial organization at the micro- and nanoscale levels (fig. 1).

The surface exhibited a relatively homogeneous appearance in terms of material continuity, with no evidence of abrupt discontinuities or major structural defects. The relief was predominantly defined by rounded features, while transitions between areas of maximum and minimum height were gradual.

The topographical configuration indicated the presence of randomly distributed morphological units, without a clearly identifiable preferential alignment. Furthermore, no filamentous formations or dominantly oriented structures were observed, suggesting a predominantly isotropic character of the analyzed surface.

Overall, the topographic image reflected a continuous surface structure, with moderate variations in relief and without extreme features such as sharp peaks or pronounced depressions.

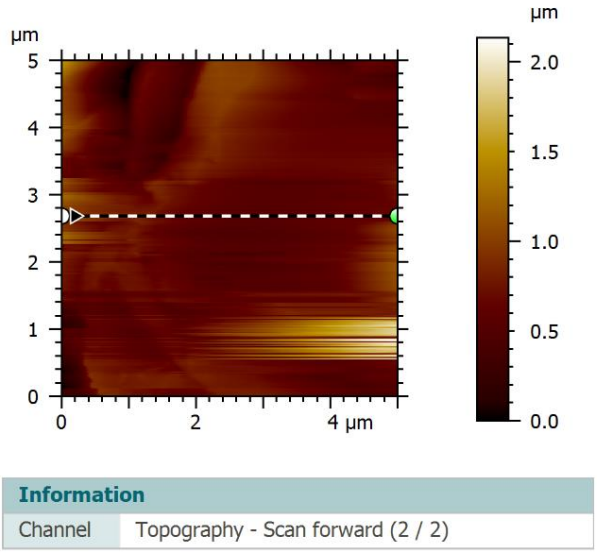

Fig. 1. Surface topography of the synthetic tissue under hydrated conditions as revealed by AFM.

AFM Deflection Image Analysis. The AFM deflection image revealed a pronounced distribution of local contrast, reflecting significant variations in the interaction between the probe tip and the surface of the synthetic tissue. Regions of differing intensity were observed, corresponding to local slope variations and fine morphological discontinuities (fig. 2).

The deflection signal highlighted structural details that were not as clearly visible in the topographic image, particularly at the boundaries between morphological units. Well-defined contours of surface features were identified, along with transition zones where surface inclination changes were more pronounced.

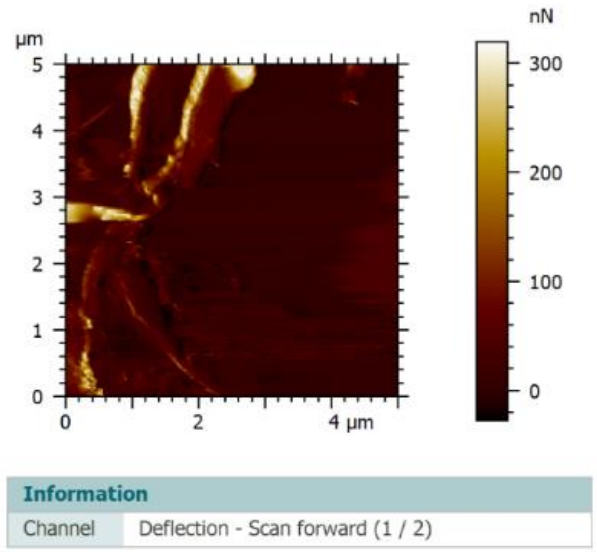

Fig. 2. Representative AFM deflection image of the synthetic tissue under hydrated conditions (5 × 5 µm scan area)

The image exhibited a granular contrast pattern, with an alternation between bright and dark regions, suggesting the presence of micro-scale heterogeneities at the surface level. No major discontinuities or evident artifacts were observed, indicating good scanning stability under hydrated conditions. Furthermore, the distribution of the deflection signal did not indicate a clear preferential orientation, supporting the predominantly isotropic character of the surface structure.

Three-Dimensional Surface Reconstruction Analysis. The three-dimensional reconstruction of the synthetic tissue surface obtained by AFM revealed a relief characterized by continuous altimetric variations, non-uniformly distributed across the analyzed area. The surface exhibited an undulating configuration, with an alternation between elevated regions and depressions, without the presence of abrupt discontinuities or well-defined dominant structures (fig. 3).

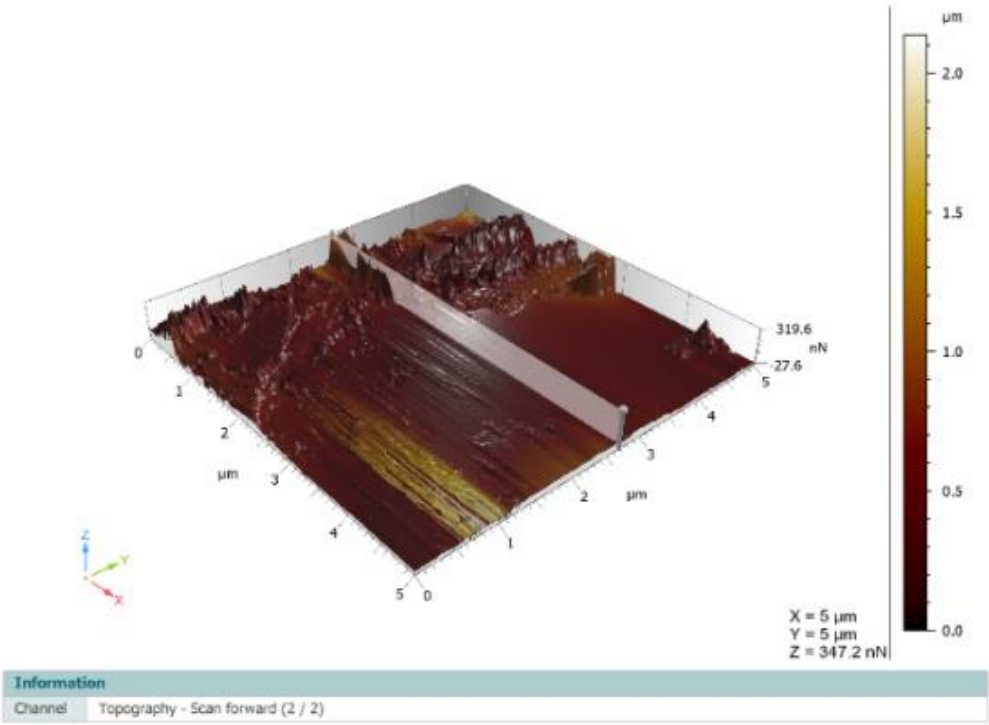

Fig. 3. Three-dimensional reconstruction of the synthetic tissue under hydrated conditions.

The morphological elements appeared to be relatively randomly distributed, without a clearly identifiable preferential orientation, indicating an isotropic spatial organization. The height of the structures varied gradually, and transitions between regions were smooth, suggesting a continuous distribution of the material at the surface level.

The three-dimensional aspect confirmed

the presence of morphological units with rounded shapes, without sharp peaks or deep depressions. The overall relief was characterized by moderate height variations, uniformly distributed, providing a coherent representation of the spatial configuration of the surface. Overall, the 3D reconstruction highlighted a continuous surface with moderate relief and without extreme heterogeneities.

Surface Profile Analysis. The surface profile obtained from a cross-sectional analysis revealed continuous altimetric variations along the analyzed distance, reflecting the undulating configuration of the synthetic tissue surface under hydrated conditions. The profile trace indicated an alternation between regions of maximum and minimum height across the entire length of the section (fig. 4).

Height differences were expressed at the nanometer scale, and the amplitude of the variations was moderate, with no evidence of sharp peaks or abrupt depressions. Transitions between maxima and minima were gradual, suggesting a continuous distribution of the material at the surface level.

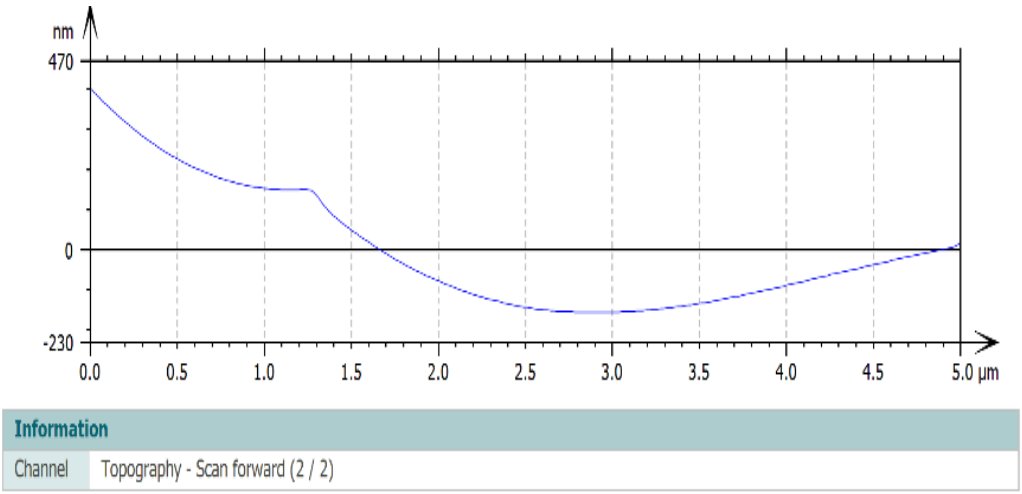

Fig. 4. Representative AFM cross-sectional surface profile of the synthetic tissue under hydrated conditions.

Along the length of the profile (corresponding to the scanned dimension, in the micrometer range), no areas with abrupt discontinuities or localized material accumulations were identified. The profile exhibited a relatively uniform character, with regular height fluctuations, indicating a balanced spatial organization. Overall, the cross-sectional profile confirmed the presence of a moderately rough surface, with uniformly distributed variations and no extreme

Surface Roughness Analysis. Surface roughness parameters derived from AFM analysis revealed a moderate level of altimetric variation of the synthetic tissue surface under hydrated conditions. The amplitude parameters (Sa = 0.1179 µm and Sq = 0.1765 µm) indicated a relatively uniform

distribution of surface heights relative to the mean plane, supporting the continuous nature of the surface relief (tab. I).

The maximum height parameter (Sz = 1.541 µm) reflected the difference between the highest peak and the deepest valley, indicating the absence of pronounced peaks or deep depressions. This observation is consistent with the topographical and cross-sectional profile analyses, where no major discontinuities were identified.

TABLE I.

Surface roughness parameters of the hydrated synthetic tissue

ISO 25178-2 - Roughness (S-L)		
S-filter (λs): None		
F-operation: None		
L-filter (λc): Gaussian, 0.0025 mm		
Height parameters		
Sq	0.1765	µm
Ssk	1.334	
Sku	7.873	
Sp	1.069	µm
Sv	0.4719	µm
Sz	1.541	µm
Sa	0.1179	µm

The dimensionless shape parameters of the height distribution (Ssk = 1.334 and Sku = 7.873) suggested a slightly skewed distribution with a tendency toward asymmetry, depending on the obtained values. This indicates a relatively balanced distribution of peaks and valleys, with a possible predominance of either protruding or recessed features. Overall, the roughness analysis confirmed the presence of a moderately developed surface relief, uniformly distributed and without extreme heterogeneities at the level of the analyzed surface.

Height Distribution Histogram Analysis. The height distribution histogram revealed a concentration of values around the central region, indicating that the majority of surface points were located close to the mean plane. The range of height values extended from negative to positive values (expressed in nanometers), reflecting the overall amplitude of altimetric variations (fig. 5).

The highest frequency was observed in the central region of the distribution, where a pronounced peak was identified, suggesting the predominance of height values close to the mean. The distribution exhibited a moderate width, indicating a relatively controlled dispersion of height values.

The shape of the histogram was relatively symmetrical or slightly skewed, depending on the exact distribution of the data, suggesting a balanced or mildly inclined distribution of peaks and valleys. No ex-

tended tails or dominant extreme values were observed, indicating the absence of major surface irregularities. Overall, the histogram confirmed the moderate nature of height variations and their relatively uniform distribution across the analyzed surface.

DISCUSSION

The surface topography observed under hydrated conditions reflects the influence of hydration on the morphological configuration of the synthetic tissue. The presence of water has been associated with a redistribution of the material at the surface level, leading to a more uniform appearance and attenuation of topographical contrast. Such behavior is consistent with previous studies demonstrating that hydration can induce structural relaxation and increased compliance in collagen-based materials (10, 13).

The rounded morphology of surface features and the gradual transitions between regions can be correlated with the compliant nature of hydrated soft biomaterials, in which water acts as a plasticizing agent, reducing stiffness and smoothing surface irregularities (14). Consequently, the interaction between the AFM probe tip and the surface is influenced by this hydrated state, resulting in a relatively “smoothed” representation of the surface relief compared to measurements performed under unhydrated conditions (15).

The random distribution of morphological units suggests the absence of a clearly defined directional organization or, alternatively, the masking of an underlying structural arrangement due to hydration effects.

This observation supports the interpretation of an isotropic structural response of the material under the experimental conditions employed, a characteristic commonly reported for collagen matrices lacking preferential fiber orientation (16).

The overall topographical appearance is consistent with a continuous and flexible surface structure, which may have direct implications for interactions with the surrounding biological environment, particularly in the presence of fluids. Surface properties such as roughness and compliance are known to influence protein adsorption and subsequent cellular behavior, including adhesion and proliferation (7,17).

At the same time, potential measurement-related effects specific to wet conditions must be considered. Capillary interactions, variations in contact forces, and hydration-induced changes in tip-sample interaction dynamics may subtly influence the recorded topographical configuration (8). These factors are well-documented in AFM studies performed in liquid environments and should be considered when interpreting nanoscale surface features (18).

The AFM deflection image provided complementary information to topographical data, being particularly sensitive to local slope variations and rapid changes in surface relief. The high contrast observed can be associated with height gradients across the surface, allowing for a clearer delineation of boundaries between morphological structures.

Under hydrated conditions, the deflection response was influenced by the complex interaction between the AFM probe tip and the hydrated surface layer. The presence of water contributes to modifications in contact forces and local mechanical response, leading to an enhancement of contrast in certain regions and attenuation in others (18,19). The well-defined contours observed in the deflection image suggest that, although the overall topography appears relatively smoothed due to hydration effects, local slope variations remain detectable and may even be amplified in the deflection signal.

This observation highlights the increased sensitivity of deflection imaging to fine morphological details, particularly at the interfaces between structural units. The granular appearance of the image can be interpreted as the result of microstructural heterogeneity of the synthetic tissue, combined with tip-surface interaction effects in a liquid environment (18, 20).

The absence of a preferential orientation is consistent with the topographical findings, supporting a predominantly isotropic structural organization. At the same time, it is important to consider that AFM measurements performed under hydrated conditions may be affected by additional factors, such as capillary forces, variations in local adhesion, and changes in tip-sample interaction dynamics (21, 22). These effects can influence the deflection signal and contribute to the observed contrast without exclusively reflecting the actual surface geometry (9).

The three-dimensional reconstruction enabled a more intuitive evaluation of the spatial distribution of height variations, confirming the continuous and relatively uniform nature of the surface observed in the topographic images. The undulating configuration can be associated with the material response under hydrated conditions, where the presence of water influences local material redistribution and

reduces topographical contrast. Rounded surface features and the absence of abrupt discontinuities are consistent with the compliant behavior of hydrated collagen-based structures, in which water induces structural relaxation and attenuates sharp height variations (20, 24).

The relatively random distribution of three-dimensional features further supports the absence of a preferential directional organization, in agreement with the observations from both topography and deflection imaging. Such behavior is characteristic of collagen matrices exhibiting isotropic structural organization under hydrated conditions, as reported in recent biomaterials studies (25).

The 3D reconstruction also facilitated the identification of spatial relationships between elevated and depressed regions, demonstrating that height variations were gradually distributed without the accumulation of critical regions. This configuration is consistent with a continuous material structure exhibiting increased surface flexibility, which may play a role in modulating interactions with the surrounding biological environment (26).

The cross-sectional profile analysis provided a quantitative perspective on surface height variations, supporting the qualitative observations derived from topography and three-dimensional reconstruction. The regular alternation between maxima and minima is indicative of an undulating surface architecture typical of hydrated soft biomaterials (27). The moderate amplitude of altimetric variations suggests a stable surface configuration, without the presence of major local defects. The absence of abrupt transitions further supports a homogeneous material distribution and highlights the influence of hydration in smoothing surface irregularities.

The smooth and continuous shape of the profile can be correlated with the compliant behavior of the hydrated surface layer, where water reduces local stiffness and contributes to the homogenization of the surface relief (28). The relatively uniform distribution of variations לאורך the entire profile length supports the hypothesis of an isotropic surface organization, consistent with the findings obtained from topographic and deflection analyses. Additionally, the absence of localized accumulations of height variations suggests a stable structural response, which may have favorable implications for the functional behavior of the material in wet environments (29).

The roughness parameters obtained were consistent with the observed topographical configuration and reflected the direct influence of hydration on surface behavior. The presence of water was associated with a reduction in altimetric contrast and a homogenization of the surface, leading to moderate values of Sa and Sq. Similar trends have been reported in recent AFM studies of collagen-based and soft biomaterials analyzed under hydrated conditions (30).

The moderate values of the Sz parameter can be interpreted as a consequence of the absence of major structural discontinuities and a stable material response in wet conditions, which agrees with the continuous surface observed in the 3D reconstruction. The shape parameters of the height distribution (Ssk and Sku) provided additional insight into the nature of the surface relief. A near-symmetrical distribution suggests a balanced presence of peaks and valleys, while slight deviations may indi-

cate a modest predominance of either protruding or recessed features. These findings are consistent with the rounded morphology and gradual transitions observed in AFM images (31).

Overall, the results indicate that under hydrated conditions, the synthetic tissue surface exhibits a more uniform and morphologically stable behavior compared to typical dry-state analyses. This surface homogenization may have direct implications for surface interactions, including adhesion phenomena and local mechanical response, which are critical for biomaterial performance in physiological environments (32).

The height distribution histogram further supported the topographical and cross-sectional findings, confirming that the surface was characterized by moderate variations and a relatively uniform organization. The concentration of values around the mean plane indicates the predominance of low-relief regions, typical of hydrated soft materials (33).

The moderate width of the distribution reflects controlled surface variability and suggests the absence of extreme heterogeneities. This behavior can be attributed to the effect of hydration, which contributes to surface smoothing and reduction of altimetric contrast (34). The approximately symmetrical shape of the histogram indicates a balanced distribution of peaks and valleys, consistent with a stable structural configuration.

The absence of extended tails or dominant extreme values suggests the lack of major defects or structural discontinuities, further supporting the continuous nature of the material. Additionally, the observed distribution is influenced not only by intrinsic surface characteristics but also by experimental conditions, including tip-surface interactions and the presence of water, which may contribute to the attenuation of height variations and the clustering of values around the mean (35).

Hydration was associated with an attenuation of topographical contrast and a homogenization of the surface relief, leading to increased compliance of the superficial layer. This aspect is clinically relevant, as hydrated conditions closely mimic the physiological environment in which these biomaterials are typically applied.

The predominantly isotropic character of the surface, together with the uniform distribution of height variations, suggests a predictable material behavior when in contact with soft tissues. Such an organization may promote a more uniform interaction with the biological environment and reduce the risk of localized stress concentrations or uneven tissue integration.

The moderate values of surface roughness parameters indicate a surface that is sufficiently active from a topographical perspective to support biological interactions, without exhibiting extreme irregularities that could compromise mechanical stability or local surface behavior. This balance may be considered favorable for processes such as cell adhesion and the initial stabilization of the biomaterial.

The height distribution, characterized by a concentration of values around the mean plane and the absence of extreme values, further supports the presence of a morphologically stable and homogeneous surface. From a clinical perspective, this uniformity may contribute to more controlled integration and predictable interactions with biological fluids and tissue components.

CONCLUSIONS

The results of the atomic force microscopy analysis demonstrated that, under hydrated conditions, the surface of the porcine-derived collagen matrix exhibits a moderately developed, continuous, and relatively uniform relief, characterized by gradual altimetric variations and the absence of major structural discontinuities.

This morphological configuration reflects a stable structural behavior and a balanced distribution of surface features.

Overall, the identified topographical characteristics suggest that the analyzed collagen matrix exhibits surface properties highly compatible with use in hydrated environments, providing a stable and uniform structural support. These features may have favorable implications for the clinical performance of the biomaterial, particularly in terms of soft tissue adaptation and interaction with the biological environment.

CONTRIBUTIONS TO THE CHARACTERIZATION OF BIOCENOSIS COMPLEX OF THE ECOSYSTEM IN THE ORAL CAVITY (Abstract): Oral biotype includes the local defense factors represented by oral mucosa, reticulohistiocytic system and saliva which opposes biocenosis composed of various microorganisms, normally achieving the state of "biological balance". **Material and methods**: The study included 23 patients with clinical manifestations of oral candidiasis admitted during the period 2014-2016 to the Dental Surgery Clinic of the Iasi "Grigore T. Popa" University of Medicine and Pharmacy. **Results**: Under favorable conditions, many non-pathogenic species become virulent in the host organism. These conditions are created using antibiotics, corticoids, immunosuppressant, antifungal, psychotropic drugs, contraceptives, radiation therapy, hormone treatment, etc. In general conditions caused by metabolic disturbances and decreased body resistance associated with microbial, vitamin and enzymatic imbalances the development of mycoses is favored. **Conclusions:** Diagnosis and correct treatment of mycoses of the oral cavity avoiding complications, oral cavity being the starting point for many endogenous infections, sepsis included. **Keywords**: BIOCENOSIS, ORAL BIOTYPE, ORAL MUCOSA, ORAL CANDIDIASIS.

Oral cavity biocenosis forms an ecological system like other natural biocenoses located in the gingival ditch and dorsal surface of the tongue, where the microbial concentration can be 100 times higher. Of these, 29 microbial species are permanently present in the oral fluid, to which others from the external environment are occasionally added, which make up the fluctuating or temporary flora (1, 2). In case of poor oral hygiene, anaerobic and proteolytic bacteria predominate. Yeasts, microscopic fungi are also present, and in case of poor oral hygiene they are present in high concentration on the dorsal surface of the tongue (3, 4).

Mycoses, diseases produced by the development of microscopic fungi in the tissues, are distinct from mycotoxicosis, fungal allergies, and infections caused by Actinomyces. The most common conditions are candidiasis C, related to the presence of blast spore fungi of the genus Candida. They may be local or general, acute, sub-acute or chronic. Certain mycoses are strictly human, but animal mycoses can be

transmitted to humans by direct or indirect contact with contaminated air and soil.

MATERIAL AND METHODS

The study included 23 patients with clinical manifestations of oral candidiasis admitted during the period 2014-2016 to the Clinic of Dental Surgery of the Iasi "Grigore T. Popa" University of Medicine and Pharmacy. The following were found: one case each (4.35%) of acute oral thrush, glossitis, candidal uranitis, pemphigoid candidiasis, geographic language; 4 (17.39%) cases with exacerbated phenomena and 15 (65.22%) cases with glossitis (tab. I).

TABLE I

Distribution of the study group by disease categories

Disease	No. cases	%
Acute thrush	1	4.35
Glossitis	1	4.35
Candidal uranitis	1	4.35
Pemphigoid candidiasis	1	4.35
Geographic tongue	1	4.35
Exacerbated clinical phenomena	4	17.39
Various forms of glossitis	15	65.22

The results were evaluated by the statistical and mathematical methods included in EPIDEMIOLOGICAL PROGRAMS (EPI-INFO).

RESULTS

In this study the following cases were recorded:

1. A 72-year-old totally edentulous female patient, who, following the extraction of her only remaining molar on the upper left hemi arcade, presented acute thrush, form located on the jugular and especially gingival mucosa in the upper cul-de-sac around the extraction site due to the antibiotic placed in the dental alveolus and on the post extraction wound;

2. In a subgroup of 15 cases of glossitis - of which one case of depapillated median tongue following penicillin treatment; one case with median rhomboid glossitis characterized by a rhomboid lesion with papillated mucosa, located in the middle of the dorsal surface of the tongue, with the great anteroposterior axis just anterior to the V region of circumvallated papillae, placed quite regularly on both sides of the median line of the tongue; a case with chronic glossitis associated with perleche/angular cheilitis, lesion characterized by a depapillated area with irregular margins at the base of the tongue on the right side; healing was obtained only after the discontinuation of antibiotic treatment and administration of a specific antifungal; 2 cases of candidal glossitis, presenting on the mid-dorsal surface of the tongue, jugular mucosa and left commissural lesions of chronic thrush in the form of leukokeratotic deposits in large spots with a carmine red contour in the center of the tongue;

3. Another case is a 61-year-old patient with a diagnosis of gastric neoplasm presenting whitish leukokeratotic deposits with irregular appearance disseminated throughout the dorsal surface of the tongue; the underweight patient was operated 2 months earlier and was undergoing chemotherapy;

4. A female patient with *chronic erosive candidal glossitis* on the whole surface of the tongue, partially covered by white leukokeratosis deposits; laboratory examination made the diagnosis of oral candidiasis;

5. Other cases: *chronic glossitis* in 6 patients, 3 of which had macroglossia and moderately scrotal tongue with superim-

posed infection with Candidal; macroglossia was also recorded in other 3 patients, teeth impressions and scrotal appearance with white Candidal deposits being seen on the margins of the tongue; *chronic erosive candidal glossitis* was diagnosed in a patient with erosive lesions on the whole surface of the tongue, partially covered by white leukokeratotic deposits; glossitis associated with candidal uranitis was recorded in a patient with Kissing "mirror" lesions. The median palatine raphe presented a longitudinal band from where white keratotic granulations come off. On the lateral aspects of the soft palate, close to the tooth cervices, there were discrete erythematous and keratotic placards corresponding to those on the margins of the tongue. Uranitis progressed in parallel with glossitis;

6. The appearance of *geographic tongue* and the smear, culture and positive germ-tube test pleaded for an over-infection with *Candida albicans*. Effective treatment consisted in the administration of nystatin for a period of 12 days concurrently with treatment to balance diabetes and increase body resistance;

7. A 52-year-old male patient with chronic lung disease treated with antibiotics and corticoids for about 30 days showed among others such subjective signs as the inability to masticate and swallow. Thus, besides dryness and burning sensation, the patient complained of pain and even altered sense of taste, worsened in the presence of acid or fermented food. The subjective and objective phenomena disappeared only after sustained treatment for 10 days and discontinuation of antibiotic and corticoid treatment;

8. A male patient with oral candidiasis characterized by large areas of ulcers very similar to pemphigus was diagnosed with chronic pemphigoid candidiasis. The lesion mimicked an oral stomatitis, with, two large superficial ulcerations with slightly irregular contours, bright-red background, partially covered by a white-yellow fibrin layer on the dorsal surface of the tongue. The neighboring mucosa was almost entirely covered by a white parakeratosis bed. The patient complained of troublesome pains and functional impotence;

9. In some patients, chronic oral thrush was characterized by episodes often triggered by the ingestion of sweet foods. The condition is a little troublesome, the general state is good, but is frequently associated with perleche, onychia with perionychia or vulvitis. Intraoral examination revealed stomatitis involving the tongue, soft palate and the jugular mucosa, glossitis being the predominant lesion, or possible associated lesions.

DISCUSSION

It is proven that under favorable conditions many pathogenic species become virulent in the host organism. These conditions are induced by the administration of antibiotics, corticoids, immunosuppressive, antifungal and psychotropic drugs, contraceptives, radiation therapy, hormone treatment, etc. Both in general conditions, favored by metabolic disturbances and decreased body resistance, as well as in local conditions due to microbial, vitamin, or enzymatic imbalances iatrogenic mycoses have been triggered (5, 6).

At present there is a growing incidence of fungal diseases and a diversification of their localization, thus becoming a multidisciplinary concern (7, 8). As the number of patients with such complains is high, there is a need for clarification on "fungal

labeling" of the described situations particularly with respect to the criteria for assessing the pathogenic implications of candida species in the oral cavity (9, 10).

Modern therapeutics, often irrational, excessive and injudicious, and aggressive for the body, gives the chance to some "opportunistic mycetes" to manifest their pathogenicity. Mycology has tracked the evolution of this pathology, bringing solutions to many problems posed by the clinical and biological diagnosis, as well as by therapeutic difficulty (11).

Correct diagnosis and treatment of these conditions is of importance both due to the highest frequency of the species in the oral cavity and the serious complications they may induce, this being the starting point for most endogenous infections (12).

It has been proven that the most common diseases are those caused by the presence of blast spore mycetes of the *Candida* genus. They may be local or general, acute sub-acute or chronic (13).

Mycoses can be distinguished not only by clinical aspect, but also by their geographical distribution, some being ubiquitous, such as *Candida*. Others require conditions and are met in limited geographic areas, being part of the import pathology.

CONCLUSIONS

Our study showed an increase in the incidence of oral fungal infections, important finding because many of them do not remain localized but can disseminate, sometimes leading to septicemic and visceral complications with poor prognosis.

Clinical manifestations in adults and the elderly are extremely diverse, imposing mandatory exams for diagnosis and treatment, as well as dispensing, with frequent recurrent forms.

Etiologically, iatrogenic mycoses ranked first, being the result of antibiotic therapy (27.8%), corticotherapy (4.9%) and psychotherapy (3.1%), thus requiring a more judicious administration of these treatments and their association with long-term nystatin prophylaxis.

Clinical manifestations in adults and the elderly are extremely varied, requiring mandatory exams to make the diagnosis and initiate a treatment, as well as follow-up given the fact that recurrences are common.

SEROTONIN - A POTENTIAL PERIPHERAL BIOMARKER IN SUDDEN INFANT DEATH SYNDROME

Although Sudden infant death syndrome (SIDS) has been related to deficiencies of the central serotonin (5-hydroxytryptamine, 5-HT) localized in the brainstem, recent serum studies have associated the elevation of serum 5-HT levels in the development of SIDS. The authors analyzed the serum 5-HT levels in SIDS infants (n=61) compared with autopsied controls (n=15), using the Enzyme-Linked Immunosorbent Assay (ELISA) test and validated it using High-Performance Liquid Chromatography (HPLC). The test results identified a significant elevation (95%) in serum 5-HT in the SIDS cohort versus control cases. Although the mechanism involving the increased serum 5-HT levels is not well defined or explained, this study clearly indicates/establish that SIDS is associated with peripheral abnormalities in the 5-HT pathway. These results instigate us to believe that high serum 5-HT may be used as a forensic biomarker in autopsied infants with SIDS with serotonergic defects (Robin L. Haynesa,1, Andrew L. Frelinger IIIb, Emma K. Gilesa, Richard D. Goldsteinc, Hoa Trana, Harry P. Kozakewicha, Elisabeth A. Haasd, Anja J. Gerritsb, Othon J. Menae, Felicia L. Trachtenbergf, David S. Patersona, Gerard T. Berryg, Khosrow Adelih, Hannah C. Kinneya, and Alan D. Michelsonb. High serum serotonin in sudden infant death syndrome. *Proc Natl Acad Sci USA* 2017; 114(29): 7695-7700).

ACUTE BACTERIAL GASTROENTERITIS AS HOSPITAL-ACQUIRED INFECTION IN PEDIATRICS (Abstract): Gastroenteritis as hospital-acquired infection represents one of the most important issue to be managed in pediatric units. **Material and methods**: The descriptive study was conducted on a group of 536 cases with bacterial gastroenteritis as healthcare associated infections (HAIs), admitted in „Sf. Maria" Children's Emergency Hospital, Iasi, during 2013-2016. **Results**: Distribution according to pathogens detected by specific investigations showed that *Campylobacter* (69.77%) was involved in most cases of gastroenteritis, followed by those determined by *Salmonella* (21.45%). Distribution by age group highlighted that children of 0-1-year-old were the most affected and *Campylobacter* was the most involved pathogen in gastroenteritis of that age group, followed by cases with *Salmonella* gastroenteritis. Children from 2-6 and 6-11-years age groups were involved in gastroenteritis with *Salmonella* followed by that with *Campylobacter*. Children of 12-18-years-old were admitted with gastroenteritis due to *Salmonella*, then *E. coli*. *Shigella spp.* was isolated in 10 cases, and *Yersinia spp.* in only 3 cases. **Conclusions**: The issue of gastroenteritis as a hospital-acquired infection remains hereafter the keystone of hospital management, as well as prevention and control strategies. **Keywords**: ACUTE BACTERIAL GASTROENTERITIS, HEALTH CARE-ASSOCIATED INFECTION, PEDIATRICS.

Healthcare-associated infections (HAIs), which were previously referred to as nosocomial infections, are an important public health problem generated by medical practice involving patients, but also medical, paramedical and non-medical staff, which ensure the functionality of hospitals. They have an important impact on the healthcare system, due to the increased morbidity, mortality, and long-term hospitalization costs (1).

The current features of HAIs in pediatric units are determined by a variety of factors: low patient age, prematurity / dysmaturity, immunodeficiency status, alteration of anatomical defense barriers, congenital malformations and/or associated pathologies, prolonged hospitalizations, increasing number of surgical interventions, the multitude of diagnostic and therapeutic procedures, some of them invasive, the abuse of broad spectrum antibiotics, often unjustified, the occurrence of bacteri-

al multidrug resistance to antibiotics (1, 2).

Early detection by screening of patients colonized or infected with multiple resistance bacteria is an important and useful intervention that can be easily implemented and can have a significant impact, increasing the population health. Bacterial screening in carriers, as part of HAIs control programs, allows the implementation of preventive measures to avoid transmission of these infections. To increase the performance of these screening programs, it is necessary to involve the clinical laboratory, hospital management staff (epidemiologist, infectious disease specialist, medical assistant specialized in HAIs control), as well as the involvement of the management team and the hospital administration (1-3).

A screening program for early detection of patients colonized or infected with multidrug resistant bacteria (MDR) at the very hospital admission could achieve several objectives such as: controlling the transmission of MDR bacteria in hospital units; reducing the prevalence of MDR microorganisms and thus reducing incidence or preventing the occurrence of serious infections (sepsis, pneumonia, etc.) in hospitalized patients, increasing awareness of MDR-associated risk among healthcare professionals, standardizing the detection of MDR bacteria in the laboratory; supporting a national strategy to control the transmission of MDR and HAIs with such microorganisms. In the hospital environment, there are many microorganisms that can be the cause of HAIs development and evolution when there is a break in cleaning, disinfection, inadequate unhygienic behaviors. The most common way of transmission of HAIs is represented by the hands of medical staff, so that, a proper hygiene of hands is the basis of any prevention and control program, with an important role in reducing the transmission of infections, as well as the dissemination of resistant germs. Hand hygiene generated many controversies, evidence-based arguments, and research. Improving patient hygiene, access to clean water, keeping HAIs under control might be key elements for reducing antibiotic resistance (1, 2).

MATERIAL AND METHODS

The descriptive study was conducted on a group of 536 cases with bacterial gastroenteritis as healthcare associated infections (HAIs), admitted in "Sf. Maria" Children's Emergency Hospital, Iasi, during 2013-2016. Inclusion criteria were the diagnosis of bacterial gastroenteritis with *Salmonella*, *Shigella spp*, *Campylobacter*, *Yersinia spp*, other bacterial infections, based on laboratory investigations and contracted during the hospitalization; the exclusion criteria were represented only by the diagnosis of viral, food, or allergic gastroenteritis.

The data were collected retrospectively from patient records and HAIs reporting files, subsequently statistically processed using the *SPSS 20.0* software. The age groups cases were processed in accordance with international standards (4).

RESULTS

Most cases of bacterial gastroenteritis diagnosed as HAIs were reported in 2015 (154 cases-28.73% of the total), and the lowest in 2013 (21.26%). There is an upward trend in their incidence (fig. 1).

Gender distribution showed a slight predominance of boys (295 cases-55.03%), only in 2014 prevailing female gender. Distribution according to pathogens detected by specific investigations showed that *Campylobacter* (374 cases-69.77%) was involved in most cases of gastroenteritis, followed by those determined by *Salmonel-*

la (115 cases-21.45%). Distribution by year of study showed that most of *Campylobacter* cases were admitted in 2015 (115 cases-30.74%) and gastroenteritis with Salmonella had an incidence peak in 2014 (43-37.39%) (tab. I, fig. 2).

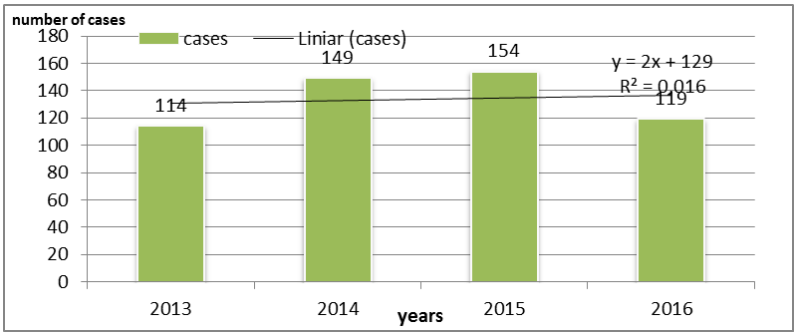

Fig. 1. Distribution of total cases by years

TABLE I

Distribution of bacterial infections cases pathogens by year of study and gender

Years / Pathogens	2013			2014			2015			2016		
	M	F	Total	M	F	Total	M	F	Total	M	F	Total
Salmonella	12	15	27	25	18	43	11	15	26	12	7	19
Shigella	1	3	4	2	2	4	0	1	1	2	0	2

Campylobacter	46	34	80	46	49	95	69	46	115	53	31	84
Yersinia enterocolitica	0	2	2	1	0	1	0	0	0	0	0	0
Others	0	1	1	0	1	1	1	2	3	3	2	5
Total	59	53	**114**	78	73	**149**	86	68	**154**	72	47	**119**

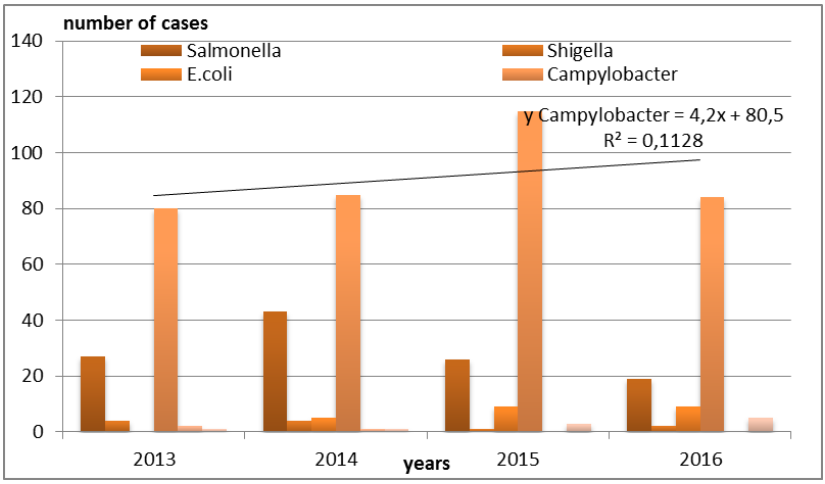

Fig. 2. Distribution of pathogens by year of study

Distribution by age group highlighted children of 0-1-year-old were the most affected (417 cases-77.79%) and *Campylobacter* was the most involved pathogen in gastroenteritis of that age group (337 cases-80.81%), with a peak of incidence in 2014 (107 cases-25.65%), followed by cases with *Salmonella* gastroenteritis (59 cases-14.14%). Children from 2-6-year age group were also involved in gastroenteritis with *Salmonella* (37 cases-53.63% of the total cases from that age group), followed by *Campylobacter* (28 cases-40.57%). Patients of 6-11-years- old suffered from gastroenteritis with *Salmonella* (12 cases-48.00%) and *Campylobacter* (6 cases-24.00%). Children of 12-18 years old were admitted with gastroenteritis due to *Salmonella* (7 cases-28.00%), then *E. coli* (11 cases-44.00%). *Shigella spp.* was isolated in patients with gastroenteritis as HAIs in our study group in 10 cases (1.86%). *Yersinia spp.* was also involved in gastroenteritis etiology, but in few cases (3 cases of our study group-0.55%) (tab. II).

DISCUSSION

Salmonella spp. has gained a distinct status over the last decades, becoming the first amongst pathogens that can contaminate the

food and the external environment involved in sporadic cases of gastroenteritis and outbreaks of food poisoning. Incidence of gastroenteritis with *Salmonella spp*. has increased greatly in almost all regions of the globe. In Western Europe, *Salmonella enteritidis* has become the dominant strain (5, 6).

Morbidity and mortality data are imprecise: there is no reporting system for *Salmonella spp*. isolated in humans, animal or food of animal origin, and the cause of death is not always the salmonellosis etiology. Only the investigation of the *Salmonella* food outbreaks can provide a clear description of this public health problem. Due to the widespread and a high probability of outbreaks and epidemics, several types of surveillance and control programs for *Salmonella* infections were implemented, such as those in Denmark, the United States, Australia and other countries. A Surveillance Program of these diseases has been implemented in the European Union since 2003, focused on food quality (7).

Diarrheal diseases with *Shigella spp*. are endemic worldwide and with extremely high levels of prevalence in undeveloped countries. Shigellosis is a very contagious disease and a frequent cause of death in children under 5 years of age. The United States is currently report a prevalence of 6-10% and the most affected age group is of 0-4 years. In Romania, the incidence of shigellosis had a decreased trend, from 130.6%ooo in 1975 to 31.8 in 1990 and to 6.7 in 2004. *Shigella flexneri* is the most intense circulation strain in Romania followed by *S. sonnei* (especially in Banat and Transylvania regions). *S. dysenteriae* has not been isolated in Romania since 1955. It is noticed that *S. sonnei* circulation is more intense in developed areas. Children were the most affected in regions where the disease is epidemic. Receptivity decreases with the age and epidemiological observations suggest the introduction of specific serotype immunity (8).

Incidence of diarrheal infections with *Campylobacter* tends to have the same position as incidences of infections caused by non-typhoid *Salmonella*. The incidence is higher in the summer season in temperate areas, but there is no seasonality in tropical areas. The morbidity evaluation and management is based on bacteriologically confirmed cases. The United States reported an incidence of 5-6%ooo. Campylobacter infections are hyper-endemic, endemic, or as outbreaks in developed countries with hygienic standards). In Thailand, *Campylobacter* infections seem to dominate the bacterial etiology of diarrheal diseases, and *C. jejuni* serotypes 36, 4 and 11 being encountered at the highest frequency. The highest rates of hospitalization for *Campylobacter* infections (74-78%) were reported by Cyprus, Latvia, Lithuania, Romania, and the United Kingdom. At the same time, Cyprus, Latvia, and Romania have the lowest number of reported cases, pointing out that surveillance in these territories manages to include only severe cases. UK reported 20 deaths of a total of 31 deaths registered in EU, in 2012. In the United States, the incidence of *Campylobacter* infections has declined towards the end of the 1990s and remains at low levels after the implementation of hygiene measures on drinking water disinfection and using chlorinated water in food industry (9-11).

In 40-90% of pediatric patients admitted in intensive care units there is an increased risk of diarrhea as HAI. Infectious diarrhea is usually more severe than non-infectious diarrhea, increasing the frequency of cardiac complications (arrhythmias) due to associated hydro-electrolytic imbalances, cardiopulmonary instability requiring vas-

opressors and mechanical ventilation or intraabdominal complications. An important problem too is the transmission of pathogens from patient to patient, from patient to healthcare worker as HAI outbreaks (12).

When a single case of *Salmonella* infection occurs, it should be checked if the infection is HAI or not. Epidemic investigations should assess food manipulation, inter-patient transmissions, or nurse to patient transmission. Standard detergents for hospitals and alcohol-based hand hygiene products are effective against *Salmonella spp*. Contact precautions are reserved for patients with incontinence or colostomy to control HAI outbreaks (12-14).

CONCLUSIONS

Our study highlighted that gastroenteritis with *Campylobacter* was most commonly reported in pediatric wards, especially in infants of 0-1-year-old and children of 2-6-year-old, followed by cases with *Salmonella*. The issue of gastroenteritis as a hospital-acquired infection remains hereafter the keystone of hospital management, as well as prevention and control strategies.

PERINEAL EXTERNALIZATION OF LATE JEJUNAL FISTULA AFTER RECTUM AMPUTATION-CASE REPORT (Abstract) Digestive fistula represents one of the most severe complications of surgical procedures performed on the abdominal area. We present the case of a 55-years-old female patient, known with a squamous cell carcinoma of the uterine cervix, for which was practiced 16 years ago a Wertheim procedure and afterwards treated according to the oncological medical protocols. In 2015 the patient was admitted in the General Surgery Department of the "Bagdasar-Arseni" Clinical Emergency Hospital from Bucharest for lower rectum tubular adenocarcinoma, diagnosed by clinical exam, radiological findings and histopathology. The patient underwent surgery and required an abdomino-perineal resection of the rectum. The patient had no indication for preoperative radiotherapy. The peculiarity of the case consisted in the development of upper gastrointestinal fistulas lately externalized through the perineal wound. The following surgical intervention could not identify the fistula, but we managed to perform an effective enteral-caecum anastomosis, with the main purpose to achieve a bypass of the intestinal breach. Postoperative evolution consisted in spontaneous closure of the intestinal fistula. **Keywords**: ENTERO-CUTANEOUS FISTULA, RECTAL CANCER, RECTUM AMPUTATION.

Enterocutaneous fistula is an abnormal communications between the gastrointestinal tract and the surface of the skin and can lead to real therapeutic management challenge. With all the progress made by modern medicine, the mortality related to enteral fistulas still remains significantly high (10-30%), especially in neoplastic or septic context (1).

Digestive fistula mainly occur following abdominal surgeries involving gastrointestinal resections followed by an anastomosis, injuries produced by drainage tubes, laborious dissections with subsidiary ischemia of the intestinal wall (2). About 15-25% of spontaneous enterocutaneous fistulas are the result of but inflammatory bowel diseases, corrosions induced by acute pancreatitis, radiation enteritis or diverticular disease (3). Inadequate nutritional support and conse-

quences of septic syndrome are the main factors involved in the morbidity and mortality of patients with enteric fistulas (4).

CASE REPORT

We present the case of a 55-years-old female, admitted to the General Surgery Department of the "Bagdasar-Arseni" Clinical Emergency Hospital from Bucharest for intermittent rectal bleeding, significant weight loss (12 kilograms in the past 2 months). The patient had a history of cervical cancer, treated with radiotherapy followed by the Wertheim procedure about 16 years ago (histopathological findings confirmed a squamous cell carcinoma), as well as a hiatal hernia surgical repair 5 years ago.

Clinical examination performed at the admission concluded with the rectal exam highlights at 3-4 centimeters from the anal sphincter a circumferential tumor with a partially rectal stenosis and bleeding when it is touched. The vaginal examination reveals a vaginal stump without local tumor recurrence.

Under spinal anesthesia was performed instrumental anal dilation and a biopsy was purchased from the endorectal proliferative process in shape of a crater about 5 cm in diameter. Histopathological findings reveal micro-fragments of ulcerated, tubular and papillary adenocarcinoma, with extensive areas of necrosis, fibrosis with granulation tissue, moderate desmoplastic reaction and necrotic debris. With this result the patient is directed to the oncology service, where she received chemotherapy. Radiotherapy is contraindicated due to the maximal doses previously received for the cervical cancer.

After the completion of the oncological treatment, an abdominal and pelvic magnetic resonance imaging (MRI) was performed, identifying asymmetric parietal thickening of the rectum wall (maximum thickness is 19 millimeters in the right lateral wall), intense irregular internal contours and an inhomogeneous structure causing an asymmetric stenosis at this level and invasion of the urinary bladder posterior wall. There were no signs of perirectal fat infiltration, vaginal stump invasion, ascites or pelvic lymph nodes involvement – $T_2N_0M_x$, stage I, Dukes A (fig. 1).

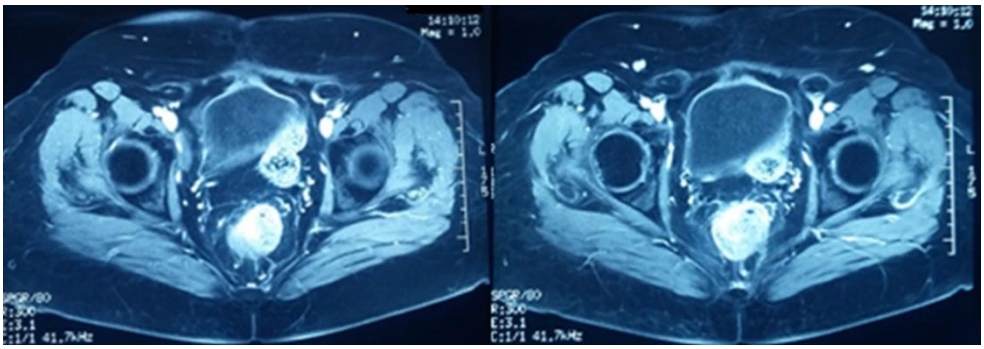

Fig. 1. Pelvic MRI – Invasion of the rectal tumor in the posterior wall of the urinary bladder

The patient undergoes surgery and were identifying a multisacular incisional hernia in the lower abdomen (after the Wertheim procedure), as well as multiple postoperative peritoneal adhesions in the inframesocolic compartment. After sectioning the pelvic peritoneum, the rectal tumor was identified attached to the urinary bladder and the dissection was performed with difficulty. An abdominoperineal resection of the rectum

was performed. The surgical procedure ends with the primary maturation of the colostomy and double drainage: peritoneal and perineal (the last one on a Pezzer tube).

Postoperatively, the patient was closely monitored, with hematological, hydro electrolytic and acid-base status rebalance in the intensive care unit and the resumption of the intestinal transit on the colostomy after 72 hours. The peritoneal drainage was suppressed 9 days after the surgical procedure. On the 10th day was observed an increase of the perineal drainage tube (serous liquid from 100 milliliters (mL)/day up to 300 mL/day). On postoperative day 11, the perineal drainage increased to 700 mL and gained a biliary aspect.

The suspicion of upper digestive fistula was raised (possible jejunal loop injury). This hypothesis was sustained by externalization on the perineal tube of methylene blue previously administered orally. A gastrointestinal transit using a radiopaque substance was performed to identify the fistula but the results were inconclusive. Considering the persistence of a large fistula flow (700-800 mL/day), interruption in intestinal transit and the appearance of an important rash on perineal skin, a new surgical procedure was required.

The accessing into the peritoneal cavity was very difficult due to adherence syndrome and edematous aspect of the intestinal loops with easy bleeding due to dissection maneuvers. In the remnant pelvic area was identified a visceral block, irreducible, adherent to the sacrum and the internal iliac vessels. The repeated attempts to dissect this block failed. Due to the elevated risk of intestinal injury, it was decided to perform an enteral-caecum anastomosis (the jejunal loop was dissected as far away as possible from the Treitz angle – about 150 cm). The enteral-caecum anastomosis was performed lateral-lateral, in double layer, respecting the peristalsis movement directions. The pelvic drainage was repositioned and the perineal drainage was checked out. The abdominal wall was closed using a substitution mesh.

Postoperatively, the patient has slowly recovered, with resumption of the intestinal transit on the colostomy 5 days later. Intestinal content continued to be externalized on the perineal drainage, but the quantity decreased gradually. On the 13th day from the second surgical procedure a gastrointestinal transit using Gastrografin was performed, revealing the small bowels loops opacified, but the anastomosis was not detected and the results were inconclusive (fig. 2).

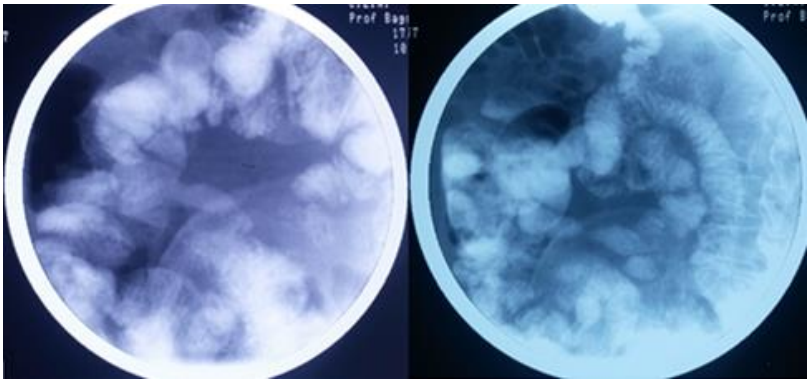

Fig. 2. Gastrografin gastrointestinal transit after the internal by-pass

After one month, the perineal tube was suppressed, the fistula flow being minimal. Wound dressing was performed daily, perineal wound healing being complete 43 days after the second surgical procedure.

The patient is discharged 46 days after the second surgical procedure, with closed intestinal fistula, slender perineal scar, normal bowel movement and discharge on the colostomy. The patient was directed to the oncology service (fig. 3,4).

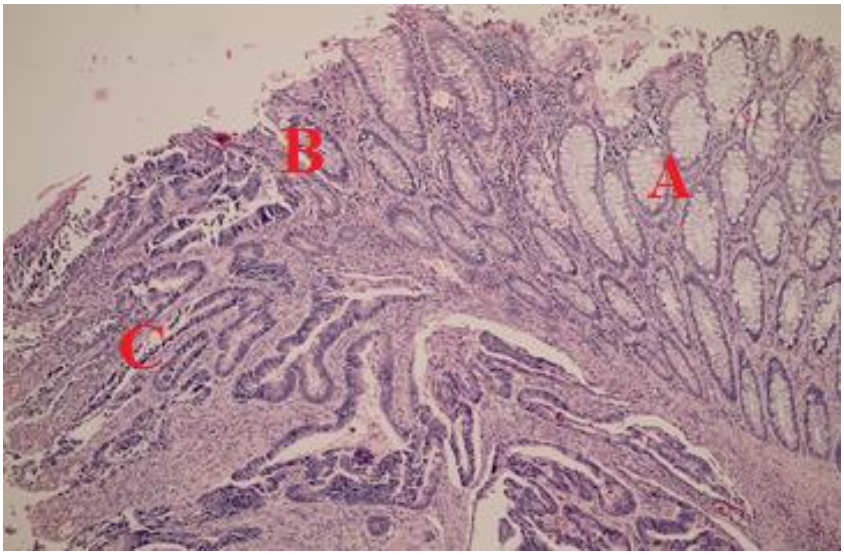

Fig. 3. Rectal tubular adenocarcinoma (A – mucosa of normal aspect;
B – area of impact between the free rectal mucosa and the tumor;
C – rectal tubular adenocarcinoma; Hematoxylin-Eosin staining - 10x

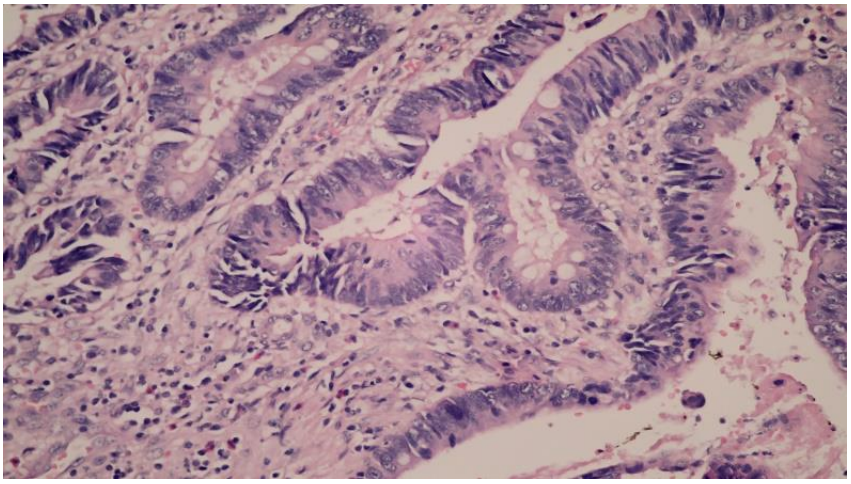

Fig. 4. Tubular adenocarcinoma – tumoral glands with chaotic architecture, mitoses and intratumorally necrosis; Hematoxylin-Eosin staining - 40x

The patient underwent surgery 18 months ago and is still in evidence of the General Surgery Department of the "Bagdasar-Arseni" Hospital, returning to control every 6 months. Following the surgical and oncological treatment, the patients had a good biological status, without clinical and imaging findings suggestive for tumor recurrence.

DISCUSSION

Perineal small bowel fistula is a life-threatening complication of abdomino-perineal resection of the rectum (5). External digestive fistula can occur after any surgical intervention performed into the abdominal cavity and concerns the general surgery departments and intensive care units, in order to overcome septic complications resulting from early intra-abdominal infection, fluid electrolyte imbalance and malnutrition (6). The therapeutic management of the enteral-cutaneous fistulas is complex, involving a balance in the nutrition, sustained drug treatment, protection of the skin against the aggressive digestive content, as well as the psychological monitoring of the patient, all these being accomplished with the help of a multidisciplinary team (7). The prognosis of an intestinal fistula depends on the anatomic location, the flow, septic complications, nutritional status, as well as the other comorbidities of the patient (8).

Choosing the optimal time for surgical intervention has not been well defined, but surgery should be delayed until the intra-abdominal and systemic conditions of the patient are propitious for major surgery (9). Usually, it is expected between 4-6 weeks, during which time about 95% of the fistulas close spontaneously (9,10).

The surgical aims for enterocutaneous fistulas are to restablish the function of the entire bowel, resection of the fistula with end-to-end anastomosis of the bowel and secure abdominal wall closure. Sometimes, previous surgical and oncological procedures such as radiotherapy can lead to a extremely difficult exploration of the peritoneal cavity and to an impossible direct approach of the intestinal fistula. In these cases, one of the few therapeutic solutions is to perform an anastomosis to bypass the fistula (6,9).

In our case, the patient presented since the onset of the fistula a large amount of intestinal output (about 700 mL/day), and lack of response to conservative treatment associated with the modified aspect of the previous irradiated intestinal loops led to performing the surgical procedure.

Regarding our patient, the disease and the changes in the intestinal wall were decisive in the development of the entero-cutaneous fistula and the suspected mechanism was a lesion due to the perineal drainage tube.

Consulting the specialty literature, we found that the externalization of intestinal fistulas predominantly through the abdominal wound or through the drainages is more frequent located on the anterior or lateral abdominal wall and the expression of a jejunal fistula through a drainage located in the perineum represents the peculiarity of this case.

CONCLUSIONS

Our case emphasizes the fact that digestive fistulas represents one of the major complications of abdominal surgery, triggering a major biological imbalance on the patient and requires a complex, interdisciplinary approach, between the surgical and the intensive care procedures. Although

most digestive fistulas close spontaneously after a certain time, there are cases where, due to the large fistulous flow, associated comorbidities or pathological preexisting conditions (neoplasia, irradiation) surgery is imposed.

ASSISTED REPRODUCTION IN ROMANIA OR RESISTANCE TO CHANGE IN A POST-COMMUNIST COUNTRY? (Abstract**):** Despite the potential role of assisted reproduction technologies (ART) to provide a recognized treatment for the ever-enlarging number of infertile couples and compensate for the Romanian low total fertility rate (TFR), the local legal and clerical community demonstrate not to be ready for cognitive assimilation of ART and for resolving the different bioethical dilemmas. What makes Romania an interesting case to be studied is the very fact that resistance to change has been correlated to notorious bioethical controversies. Therefore, the purpose of this communication was to explore endogenous and exogenous factors that may influence resistance to change, social representation of ART, as well as to observe and understand reasons for the absence of a coherent and systematic law in this field of medicine a law which should address the Romanian social, moral and cultural beliefs and values. Consequently, we have observed that after 42 years of communism and 28 years since the Revolution, the relative apathy at legislative level has been driven by psychosocial factors such as respect for traditions, conformist behavior and fear for the unknown, which have also conducted to social duplicitous behavior having generated undesired international notoriety. **Keywords:** ART, LEGISLATION, BIOETHICS, POST-COMMUNIST DEMOCRACY, RESISTANCE TO CHANGE, ROMANIA.

DECREASING FERTILITY IN ROMANIA–THE NATIONAL AND EUROPEAN CONTEXT

Since 1970, the European statistics have been reflecting a sharp unprecedented fall in the TFR within its 27 European countries. The existent demographic crisis is nothing but a predictor for the imminent economic decline, translated by the accelerated speeding up of population ageing, and implicitly at increased ratio of inactive population relying on the working population (1). The current total fertility rates are situated below replacement level, which is a generalized process all over Europe. The latest projections provided by Eurostat (2, 3) indicate the Central and Eastern Europe and the Baltic states as displaying the lowest total fertility rates. The same low fertility rates are also to be found in certain West European countries, such as Germany (1.36), Spain (1.35), Portugal (1.35).

The main factors for the declining TFR are related to educational attainment, economic security and careers (4). In the ex-communist countries, particularly in Romania, this demographic phenomenon is also a result of the frustrations caused by the deprivation of basic human needs. Thus, the low fertility rate can be regarded as a negative indicator of the quality of its people social life. The decrease of families' income correlated with the increase of the estimated costs for raising a child leads to voluntary and autonomous delaying in planning the first pregnancy until economic stability is possible. On the contrary, in the occidental countries the factors leading to low TFR reflect the fact that the development of these societies has supplied new life opportunities, changing individual values regarding personal goals, family formation and religion. Therefore, in contrast with the Romanian pro-family ideology which promotes family as the fundamental institution for the survival of the society, the individual has become the central element of social life in the West European countries (5).

Moreover, postponing parenthood due to social reasons unfortunately overlaps the biological fertile period and, consequently, diminishes the chances of conceiving. The decline in female fecundity is clinically relevant from mid-30's, when, even assisted reproduction therapy cannot compensate for the decreasing fertility potential associated with postponing childbearing. This delay has led to an increase in permanent involuntary childlessness (6, 7).

In Romania, frustrations related to the social and economic conditions are deeply rooted in the communist era. The infamous 770/1966 Decree has become a referential proof of the propagandistic communist aggressiveness against human rights as the Romanian women were "de-individualized" to the extent that they seemed to have no authority over their own body. They were forced to regard their own womb as belonging to the state and not to themselves (8). Even though the Decree, aiming to increase the fertility rates, had banned the use of any contraceptive methods and any form of abortion, the Romanian women found their own methods of resilience. While in 1967 the fertility rate doubled, reaching the maximum average value of 3.7 children born per woman, in 1973 it declined again. During the dictatorship of Ceausescu, the mortality rate among pregnant women became the highest in Europe. During the period 1966-1989, medical complications caused by illegal abortions resulted in the death of 9452 women (9). As a radical reaction to this death sentencing decree, the very first law promulgated after the 1989 Revolution was The Law-Decree no. 1/26.12.1989 that allowed abortions in the first 3 gestational months.

Therefore, the prevalence of declining fertility has become a general feature of the ex-communist countries having adopted pro-nationalist politics in the communist era. For this reason, Romania disclosed one of the lowest birth rates with an average score of 1.25 children per woman in 2011 (3). Above all, infertility has become a subject of major concern in this country. Under these circumstances, in the post-communist era, the Romanian medical community has been challenged to adjust their professional competencies to the new needs of the society to provide equitable access to optimal care for the Romanian population affected by infertility. Consequently, since 1995, when the first IVF center was officially inaugurated, there have been 24 authorized

IVF centers that have been accredited by the National Transplant Agency, the Romanian Competent Authority. Despite the professional performances achieved by the medical teams of the Romanian IVF centers, the society has demonstrated not to be ready for assimilating the new technologies and resolving the afferent bioethical dilemmas so far.

The current communication provides a retrospective overview of the evolution of assisted reproduction in Romania. Our longitudinal approach is meant to identify the endogenous and exogenous factors that have influenced the resistance to change, the social representation of ART, as well as to observe and understand reasons for the absence of a coherent and systematic law in this field, a law which should address the Romanian social, moral and cultural beliefs and values.

Therefore, the objectives of this communication have been transposed into the following research hypotheses:

1. The poorly understood bioethical challenges raised by the field of medically assisted human reproduction have consolidated resistance to change.

2. The traditionalism specific to the Romanian society has determined a significant delay in the promulgation of a special law regarding medically assisted human reproduction.

Subsequently, to verify the two hypotheses, we have examined the mass-media documents related to ART practice in Romania, the published legislative projects and documents issued by the Romanian Parliament, the current regulations related to ART, as well as the web pages of the Bioethical Commission of the Romanian Orthodox Church, National Agency of Transplant and of the Ministry of Health.

BIOETHICAL CHALLENGES – A TOO LIBERAL PERSPECTIVE ON HUMAN REPRODUCTIVE RIGHTS?

Regarding new reproductive technologies, Romanian contemporary society has not fully embraced the medical innovations in the field. As Serge Moscovici (10) points out, the way that science penetrates society implies a discontinuity which represents a necessary precondition if any innovational scientific knowledge is to enter "the society's laboratory", "where all forms of knowledge acquire a new epistemological status in the shape of social representations." As many social issues, such as organ donation and transplantation, biotechnology, human rights which have been studied in the social representation field have always attracted expansive media coverage and controversy (11), we have analyzed the way ART are reflected in the national media, which has a high exponential degree and is so influential in shaping public opinion. We also have considered the fact that social thinking filtrates and organizes information and events per the confirmation or the invalidation coming from the exterior reality. Regarding this matter, we will illustrate the evolution social representations of assisted human reproduction in Romania as it emerges from the national media that has led to widespread public debates on the social, moral and ethical implications of this kind of scientific progress.

As dynamic elements of knowledge, social representations refer to the ideas, concepts and knowledge shared by the members of the same community and are elaborated in conformity with the phenomena that constitute the center of the social life and represent the object of polemics and changes. Therefore, they represent a set of concepts

generated in the daily life denoting the myths and beliefs systems in traditional societies. Once created, they "lead a life of their own, circulate, merge, attract and repel each other, and give birth to new representations, while old ones die out" (12).

The changes caused by the communist fall have had consequences on the way people perceive their own lives, as well as on the way they perceive the individual and the society they live in. "Change does not display in a spectacular way and is escorted by stamps of resistance to change" (13). That is why change and resistance to change may be considered the two sides of the same coin.

Despite the low TFR in Romania, which could be a representation of the devaluation of the family concept, procreation still represents the center of social life. Accordingly, the increasing incidence of infertility diagnosis among the Romanian population has forced the medical community to direct their professional competencies towards assisted human reproduction field to provide optimal care for affected couples. However, the implementation of innovative technologies of medically assisted human reproduction in Romanian traditional society has determined resistance to change due to specific social, religious barriers. This can be explained by the fact that human reproduction raises important and essential challenges in the social, moral and civic development of the post-communist Romanian society, as "of all the structures composing the human organism, the reproductive system has special societal sensitiveness" (14). Consequently, assisted reproduction technologies have become a controversial medical practice in this country with a traditional Orthodox predominant society. Searching for data in the Romanian and international media documents revealing the public opinion on this matter, we have discovered that most of the articles include information related to bioethical dilemmas, such as the social age deadline for childbearing, the commercial traffic of human cells and mercantile surrogacy.

The most famous cited example related to the use of the assisted reproduction technologies in Romania is the case of Adriana Iliescu, who, in 2005, at the age of 66, gave birth to a child after having received IVF therapy. Thus, she became the oldest mother in the world and her story created a lot of bioethical controversies at that time. The ethical issues residing in this matter are associated with the medical experimental practice, but also with the individual's autonomy, as well as with the individual's right to privacy and reproductive choice. Refusal to assist women requesting ART, even if they are far beyond their natural reproductive limits, could be denial of their decision-making autonomy and of their own reproductive rights. However, recent publications referring to the community attitude towards pregnancy at postmenopausal women indicate insignificant support for this practice. Per most published surveys, the accepted age limit varies between 50 and 55 years of age (14, 15). Furthermore, the public disapproval of the sexagenarian mother may have also induced perception modifications in relation to reproduction, family, and maternity representation.

The "black list" of bioethical deviances can continue with the example of the "reverse traffic" of donor oocytes (16) and with the example of surrogate mothers who rent their uterus in exchange for large amounts of money, all made public on the internet and in the newspapers, clearly

specifying the requested price. To date, surrogacy has not been regulated by law, and thus the proliferation of this highly controversial and "financially profitable" practice.

The commercialization of human cells and commercial gestational agreements on the black market offend a series of ethical principles such as those described by Mykitiuk and Nisker (17), namely "respect for human integrity and dignity through the non-modification and non-commercialization of the person, her or his bodily parts, tissues, substances and processes; protection of vulnerable persons from coercion or inducement; and respect for the patient-physician relationship by avoiding a conflict of interest between the two parties."

On one hand, many of the advances in life sciences and biotechnology field are being a great opportunity to enhance our life through the alleviation and prevention of medical conditions. On the other hand, there has been a high degree of "concern and resistance to some of these developments, particularly about their potential uses (and abuses) of genetic information and genetic transformations" (11).

Romanian women's mercantile decisions regarding their reproductive capacity are an integral part of a more complex process which was explained by Nahman (16) as a response to the repressive probirth increase politics previously presented. Egg donation and surrogacy may also be viewed as "both a continuation of the conscription of women's bodies (by and for science and business) and a break with paternalistic control over women's bodies" (16).

The mentioned bioethical paradigm cases have turned into arguments against the acceptance of assisted reproduction technologies and have contributed to the development of stereotypical responses. Under a similar "halo effect" (18), a cognitive bias by which we make an overall judgment on something in the view of a prominent feature. Public opinion evaluated new technologies through the perspective of the bioethical objections portrayed by the media. "Stereotyping is, by definition, a generalization process which may become prejudicial per the circumstances in which it is used. The categorical labeling may take distance from the reality, even if it derives from it. Stereotypes are reversed, transfixed and rigid social representations. They are constituted in each social and cultural context, determined by a given reality. They are fed by the social memory, traditions and rituals, by mutual symbols" (19). Therefore, negative stereotypes lead to prejudices and become important factors in the development of resistance to change.

TO LEGISLATE OR NOT TO LEGISLATE?

Above all, the controversies generated by these examples are very eloquent for the direct and indirect consequences of the lack of an exhaustive law in the field of ART. These three paradigm cases are impregnated into the social cognition and have drawn attention to the need of an ART specific law. Despite the previous initiated law there was no trigger for local authorities to forward legislative projects and no law has been promulgated so far.

However, ART is not practiced completely outside a legal framework. The existent legislative coordinates represent the result of our adjustment to the European standards and requirements, because Romania becoming an EU Member State in 2007.

Accordingly, under the Law no. 17/2001, Romania has ratified the Convention for the Protection of Human Rights and Dignity of the Human Being about the Application of Biology and Medicine: Convention of Human Rights and Biomedicine, signed at Oviedo on 4th April 1997, and its Additional Protocol, signed in Paris at 12th January 1998. Moreover, Law No. 95/2006 on Reform on Public Health – Title VI: The Storage and Transplant of Organs, Tissues and Human Cells for Therapeutic Purposes, with Annexes I-XIII, and the Methodological Norms for the application of the Law stipulates general provisions referring to the use of the reproductive cells, with the application of the EU Tissue & Cells Directive 2004/23/EC. The mentioned provisions forbid financial payment for donated reproductive cells.

Furthermore, per the Ordinance No. 79/2004, the activity of human organs, tissues and cells is organized and controlled by the Ministry of Health, and the National Transplant Agency was founded to exercise these specific duties such as the coordination of procurement, processing, storage and transportation activities for human tissues and cells based on therapeutic use in Romanian territory. The National Transplant Agency is also in charge of the initiation and management of the National Transplant Register and with the proposal for accreditation to the Ministry of Health of ART units which are authorized to carry out sampling and/or transportation of human organs, tissues and cells for therapeutic purposes, as well as with monitoring their activities in the specified field. The list of the regulations in the field may continue with another two decrees: Decree No. 1242/2007 of the Ministry of Public Health on the approval of standards for the selection and evaluation of tissue and cell donors, the alert systems and emergency procedures, the qualification of the personnel of tissue and cell banks, the quality, import and export of human tissues and cells, and the relationships between tissue and cell banks and third parties. Decree No. 1763/2007 of the Ministry of Public Health provides standards for donation, sampling, testing, processing, preservation, distribution, coding, the traceability rules of tissues and cells of human origin used for therapeutic purposes, and notification of serious adverse incidents and serious adverse reactions occurring during their processing.

Moreover, articles 441-446 of Law No. 287/2009 regarding the new Civil Code encompass provisions related to the third-party reproduction. Firstly, regulated in Romanian law, per article 441, medical donor assisted procreation provides solutions for the heterosexual couples and/or single women who want a child and are not able to conceive naturally, and who shall act as parents of the child so conceived. By providing single women the opportunity to have babies, the new regulations may be considered quite a permissive approach. The new Civil Code also establishes the juridical filiation regime of children conceived through medical assisted reproduction technologies. This way, there will be no affiliation bond between the donator and the child thus conceived, and parents importantly will always be those who have resorted to assisted reproduction technologies. Consequently, the law stipulates the obligatory existence of consent to be given in front of a notary who will explain the consequences of their act related to the future child's affiliation, in terms of highest confidentiality. Until the time of the assisted conception, been undertaken this

consent will remain void in case of death, application for divorce, the separation, or of its revocation by the beneficiaries. The child thus conceived will have the same rights as a naturally conceived baby. However, the new legal framework does not explicitly define the medical techniques specific to third-party conception. Therefore, article 447 stipulates that the third-party donor donation and subsequent use, the juridical conditions, and informed consent related to procedure will be regulated by a special law.

Considering the presented legislation as well as other general regulations related to good practice in scientific research, technological development and innovations, the data processing and protection, the patients' rights, and medical deontology fields, we find that regulation of ART in Romania is fragmented and dissipated in various and numerous norms and regulations, and yet, in spite of this abundant documentation, we ascertain that the challenges of this medical field are still not sufficiently covered, as the current legal provisions in force have a significant delay in comparison with the accelerated scientific medical progresses. Accordingly, because this deficiency and the current high incidence of infertility as a medical condition, beginning with 2003, there were six consecutive legislative projects that entered the legislative circuit, but none of them has succeeded in being promulgated so far.

The first three projects displayed similar characteristics, and were definitively rejected because they proved to contain many unconstitutional articles, a precarious elaboration, with contradictory and inaccurate provisions both in terms of medical accuracy, as well as in terms of legislative technical requirements. Taking into consideration all the past amendments, the fourth project entered the Parliament's circuit with a view of approval in 2011. Therefore, the draft included the themes of gestational mothers, donated gametes, and penalties for commercialization and scientific abuses. It also encompassed provisions related to the equitable access to reproductive health- care services. Although the project seemed to be the best version to have ever entered the legislative circuit, surprisingly, it was withdrawn by the initiator. Simultaneously, the Minister for Health released the National IVF/ET Subprogram, which partially compensated the expenditures for one IVF cycle treatment from the health insurance funds for 800 married couples, annually. Eligibility criteria for obtaining access to Medically Assisted Reproduction (MAR) treatments were established and reimbursement provided only if criteria were fulfilled: the marital status (the couple had to be married for at least two years); the Romanian citizenship (at least one of the partners had to be Romanian, with a stable home address in Romania); the social insurance (at least one of the partners had to be socially insured for at least the last two years); previous children (none of the partners was supposed to have a living child); autologous couple (oocyte, semen donation and surrogate mothers were excluded); maximum age of woman (the woman had to be 24-40 years old), BMI (had to be between 20-30); normal ovarian reserve (determined by the values of FSH and AMH). Per the National Transplant Agency, 11 ART Institutes were included in the National IVF/ET Subprogram, and there were 1499 married couples who subscribed to this program until August 2012 (20). At the time of writing, the Subprogram has stopped, as no

funds are available. To make things worse, the legislative project on health-care reforms, under current public debate, eliminates this compensation for ART treatment.

Meanwhile, after the failure of the four legislative projects, and under the circumstances that Law No.71/2011, of applying Law No. 287/2009 regarding the new Civil Code, imposes the adoption of a special law regarding the third-party donor assisted reproduction, a new legislative draft in the field was put forward. The new proposal did not sufficiently cover the third-party donor reproduction issues. Although the initial form of this project was changed, and another modified draft was approved to be under debate in the Parliament, the current project is on stand-by position now because of the pre-established legal procedures and terms, and because of the recent electoral and political changes in Romania.

ROMANIAN OPINION GATEKEEPERS

To identify the factors leading to change or to resistance to change, we will examine the correlations between the Romanian most influential institutions and people's behavior and perceptions related to procreation. Per Eurobarometer's 68.2 (21) and 72 (22), as for the perception of the national institutions, Romanian people trust the Church and Television with the highest degree of confidence. This way we have the possibility to assume that the two institutions have a powerful social influence on the way Romanian society perceives its surrounding reality.

Having children is a fundamental traditional value in Romanian society, which is one also promoted by the Romanian Orthodox Church. To date, there is no explicit official position related to medically assisted reproduction. The Romanian Orthodox Church's public interventions on this topic are directly correlated with the bioethical deviances generated by the extreme situations mentioned above which gave the Church representatives the opportunity to pronounce themselves against this medical practice. It is noteworthy that the Bioethical Commission of the Romanian Orthodox Church considers the practice of tissue and organ transplantation as one of the highest forms of contemporary medical practice, which transforms pain into hope for more life. It is medical practice that the Church blesses if, by transplant, the crisis determined by the absence of any other healing solutions is resolved and normal life is given back to a person, without taking it away from another person. Nobody should be killed so that somebody else should live (23).

Surprisingly, the same document contains one reference to human embryos as unacceptable, since the embryo, although a living being, is incapable of expressing consent. Therefore, the Romanian Orthodox Church indirectly and tacitly displays a certain degree of tolerance towards new technologies in the field. On the other hand, the Romanian Orthodox Church has taken a firm position against abortion, but, despite this, abortion is legal in Romania (24). Interestingly, abortions rates from this country have declined in comparison with prior decades (2). From a religious point of view, abortion is a capital sin, but, on a more general level, it is also a consequence of the direct effects of the precarious economic and social conditions which do not foster family policies enough. History has taught us that restrictive norms and legislation do not have the expected results.

Consequently, considering the Romani-

an Orthodox Church's relative tolerant attitude towards ART and its very influential power, we assume that the religious traditionalism specific to this country is not a primordial factor leading to the delay of regulation in the MAR field.

On the contrary, the continuous bombardment with ART-related news from the Romanian mass-media devalue these techniques by attributing negative connotations to them, constantly reiterating the bioethical issues related to reproductive tourism, commercialization of human gametes and mercantile gestation. This leads us to assume that public opinion has selectively and distortedly retained mass-media information related to assisted reproduction, and information induces resistance to change.

We have noticed a direct correlation between perception and behavior related to ART. Overall, Romanian society is a conformist and imitative society, so, on an individual level, there is the tendency to fashion one's opinions per the group norms. Therefore, the perception of ART is modeled per the group norm. The clear majority of the population which do not have fertility problems become a reference group who does not have to resort to assisted reproduction services to procreate and for whom "ART may not fit into their ideological definition of family" (25). While the infertile population constitute a dispersed and stigmatized minority, the clear majority of the population is inoculated with the mass-media messages and maintains a non-critical and passive attitude on this kind of information. That is why the public debates launched by the Ministry of Health are practically inexistent, even if the ratified Convention from Oviedo urges that a legislative project in human reproduction field should be accompanied by such debates.

However, the reality is that per the National Transplant Agency, between 2009 and 2011, 10,105 couples were reported to have received assisted reproduction procedures with partner donation, and 898 patients were reported to have received assisted reproduction procedures with the involvement of a donor (26). The increasing number of couples who resort to ART treatments to conceive underlines the fact that the population affected by infertility is becoming conscious of the fact that ART is a pertinent solution to their health problem.

In contrast, Eurobarometer 72 (22) showed the Romanian population perceives national political institutions with the lowest confidence level among other official authorities and demonstrates discontent towards the inability to provide and implement prompt solutions for the current social and economic problems. It is clear the political structures have not sufficiently mobilized themselves to have a law promulgating the assisted reproduction field, in concordance with the existent democratic, ethical and socio cultural values with which ensure equal access to reproductive health-care services.

CONCLUSIONS

In Romania, twenty-three years after the end of communism, the receptivity to the imperative of change displays an asynchronically pattern, often being associated to different reactions of rejection. Respect for traditions, dependence on concepts assimilated through the initial formation, conformist behavior, dependence on majority's opinions, fear for the unknown, refusal caused by ignorance represent the psychosocial factors which block the change path (27).

Nevertheless, about the assimilation of ART treatment into the social cognition, we assume that the technological progress has functioned as a change agent and has modified the social representation of ART, particularly if we take into consideration the increasing number of IVF centers, and implicitly the increasing number of the couples resorting to ART treatment.

On the political level, in the context of a long-lasting transition period, the current situation regarding ART denotes a perpetual procrastination, as well as the adoption of a latent attitude of indifference, reserve and withdrawal towards the demographical decline and towards the increased prevalence of infertility among the population of fertile age. A society without legislation on bioethical problems adopts "the liberal position that every citizen should decide to his or her moral conviction." (28) The delay of a law to democratically and constitutionally regulate the Romanian reproductive rights underlines the fact that in Romania the democratization process has a slow, heterogeneous, evolution, with numerous endogenous socio-economic and political obstacles.

Therefore, considering the moral, spiritual, social and cultural parameters, it is imperative that the next legislative project should meet the specific requirements and bioethical principles, according to the collective values and beliefs, in order to defend every individual's basic rights to procreation, and, implicitly, to decision-making autonomy, human dignity and integrity. Otherwise, ART will continue to receive an unfavorable and controversial social representation instead of becoming a medical treatment for a World Health Organization, (WHO) recognized condition, a medical treatment facilitating what is a basic human right, the right to a family.

PANCREATICODUODENECTOMY IN PATIENTS WITH HEPATIC ARTERY ANATOMIC VARIANTS: TAILORING, PERIOPERATIVE CARE AND SURGICAL OUTCOMES (Abstract). **Introduction:** Pancreaticoduodenectomy (PD) is the procedure of choice in patients with tumors of pancreatic head or periampullary region. Hepatic artery anatomic variants (HAav) are frequently encountered during PD. **Aim:** To evaluate the incidence of HAav in a series of PDs and their consequence on technical tailoring and outcome. **Material and methods:** Forty-five patients with HAav were identified in a consecutive series of 140 PDs for periampullary and pancreatic head tumors performed between January 1, 2007 and December 31, 2015. The groups with or without HAav were compared in terms of operative approach, complications and survival. **Results:** All patients underwent Whipple procedure, with right posterior approach for those having HAav. HAav was spared without damage in 41 cases. Four patients in whom the HAav were either sacrificed (2) or damaged (2) required arterial reconstruction. **Conclusions:** HAav are frequently encountered during PD. Its safeguarding is mandatory but in malignancy it can be damaged or sacrificed, hence arterial reconstruction is required. HAav have no negative impact on surgical morbidity and outcome. **Keywords:** PANCREATIC CANCER, PERIAMPULLARY TUMORS, PANCREATICODUODENECTOMY, POSTERIOR APPROACH, VASCULAR ABNORMALITIES.

Pancreaticoduodenectomy (PD) is a challenging operation and the procedure of choice for tumors of pancreatic head and periampullary region but also for some benign lesions (1, 2). However, it is associated with a high morbidity rate of up to 50 % (2). The most feared postoperative complications are anastomotic leakage at the site of pancreatojejunostomy or hepaticojejunostomy and post pancreatectomy hemorrhage (1). Hepatic artery anatomic variants (HAav) are reported to occur in up to 49% of patients and therefore preoperative assessment of liver arterial supply is essential to prevent unnecessary complications during PD (3). Damage or ligation of an aberrant artery may cause bile duct or liver ischemia which can result in breakdown of the bilioenteric anastomosis and liver dysfunction and abscesses (4). Obstinate handling while trying

to spare HAav may result in damage to the vessel adventitia and thus make it prone to pseudoaneurysm formation, so much the more in the presence of pancreatic fistula (5). That involves a higher risk for bleeding. Otherwise, attempts to safeguard the anomalous vessel may also hinder radical oncological resection (4).

Nowadays, Michels and Hiatt international classifications of hepatic artery anomalies are the most common used (6, 7). In both classifications, an aberrant right hepatic artery (RHA) is the most common reported abnormality. Michels makes a distinction between a replaced (Michels type III) and accessory RHA (Michels type VI) arising from the superior mesenteric artery (SMA)(6). This vessel may course posterior to the pancreas, within the pancreatic parenchyma or along the ventral side of the pancreas and its reported incidence vary from 7 to 21 % (8). An aberrant RHA is the most frequently encountered vascular abnormality during PD and due to its course, it is the most susceptible to intraoperative damage and tumor involvement (8). Classically, PD is performed with transection of the pancreatic neck before the retroportal lamina dissection close to the SMA origin. Early right posterior approach PD allows a better assessment of the variant pattern of arterial blood supply to the liver, proper mobilization of the specimen from the vessels before any pancreatic or digestive division and, if necessary, safe venous clamping (9). Our study aimed to underline the implications of an abnormal HA on the PD technical approach, morbidity, the surgical outcome.

MATERIALS AND METHODS

A consecutive series of 140 PDs was performed between January 1, 2007 and December 31, 2015. HAav were identified on preoperative computed tomography. The 16-slice MDCT protocol included bi-phasic examination after intravenous contrast injection (100 mL, 350 mg I/mL, injection rate 3-4 mL/s) and post-processing with MIP and volumetric reformatation. Forty-five patients were identified with HAav and in this group (group 1, no=45; 35%) a right posterior approach PD was performed. The operative parameters, complications and survival were compared with those recorded in group 2 (95 patients without HAav, 65%) (tab. I).

TABEL I

Patient characteristics for the group with or without HAav

Patient characteristic	HAav group		Non HAav- group		p-value
Mean age (SD), years	61		62.2		0.15
Males, n (%)	24	(53.3)	49	(51.6)	0.89
ASA classification n (%)					
I	12	(26.6)	20	(21)	0.30
II	27	(6o)	57	(60)	0.85
III-IV	6	(13.4)	18	(19)	0.27
Co-morbidity, n (%)					
Cardiac	8	(17.7)	20	(21)	0.25
Hypertension	9	(20)	21	(22.1)	0.71
Pulmonary	4	(8.8)	12	(12.6)	0.09
Diabetes mellitus	6	(13.3)	15	(15.7)	0.39
Malignant disease, n (%)	38	(84.4)	81	(85)	0.87
Benign tumor, n (%)	7	(15.6)	14	(15)	0.27

Operative technique. The standard operative procedure for the PD was the Whipple–Kausch operation. All the patients having HAav (group 1) underwent posterior approach PD.

Briefly, after resectability had been assessed, an extensive Kocher maneuver, large opening of the lesser sac, isolation of the superior mesenteric vein at the inferior edge of the pancreas, exploration of the hepatic pedicle, had been carried out. Behind the pancreas, extensive early dissection exposes the origin of the superior mesenteric artery in the angle between the left side of the inferior vena cava and the left renal vein, and highlights the plane between the SMA and the SMV. This exposure enables a safe removal of the retro portal lamina (including connective tissue, perivascular neural plexus, lymph nodes belonging to posterior pancreaticoduodenal vessels), which implies the dissection of the SMA on its right and posterior sides along 3-4 cm. This is the surgical step during which the origin of a RHA (accessory, replaced, totally replaced common HA) arising from the SMA is properly distinguished. Upon discovery, the aberrant vessel is dissected upwards to the hepatic pedicle in the attempt to spare it or to assess tumor involvement. In this case, the vessel can be resected and reconstructed. Reconstruction was performed by retrocolic end-to-side "duct-to-mucosa" stented pancreaticojejunostomy, hepaticojejunostomy and gastrojejunostomy. Octreotide was routinely administrated in the HAav group (posterior approach) and only in cases of soft pancreas or non–dilated Wirsung duct in the non-HAav group.

RESULTS

Patient characteristics in the two groups are summarized in table I. There were no significant differences in terms of age, sex, American Society of Anesthesiologists class or comorbidity. The underlying disease requiring PD was the same in both groups and the malignant disease occurred in 84%, and 85 % cases, respectively. Surgical variables did not differ between the two groups (tab. II).

TABLE II

Surgical variables in the two groups

Operation	HAav group (n=45)		Non-HAav group (n=95)		p-value
Whipple, n (%)	0	(0)	95	(100)	
Posterior approach Whipple, n (%)	45	(100)	0		
Average surgery duration (SD), minutes	310		298		0.94
Median blood loss (SD), mL	1120		1010		0.89
HAav-handling					
Spared	41	(91)			
Accidentally damaged or ligated n (%)	2	(4)			
Sacrificed n (%)	2	(4)			
Reconstructed n (%)	4	(8)			

In four patients with HAav (8%), the aberrant vessel was accidentally damaged (n=2) or willingly sacrificed for oncological reasons (n=2). For the two damaged

arteries, primary closure with 6-0 prolene was performed. The two totally replaced common hepatic arteries sacrificed for oncological reasons required reconstruction using a reversed splenic artery.

Hepatic artery variants. The most common variations were replaced RHA (rRHA) (n=22- 48%) and accessory (accRHA) (n=16- 37 %) - Hiatt type III. A replaced common hepatic artery (rCHA) - Michels type IX, was encountered in 4 cases (8%). Two cases (4%) of rRHA and a left hepatic artery (LHA), and one case (2%) of accRHA and LHA were also disclosed - Hiatt type IV.

Short term outcomes. There were no differences in overall surgical morbidity and in the rates of any of the surgical complications between the two groups (tab. III). The incidence of complications related to the presence of HAav (hemorrhage, hepaticojejunostomy fistula, intraperitoneal abscess), were comparable in both groups. Hospital mortality, relaparotomy rate and length of hospital stay did not differ between the two groups.

TABLE III

Short-term outcome after PD in patients with and without HAav

	HAav group (n=45)		Non-HAav group (n=95)		P-value
Surgical complications, n (%)	24	(53.3)	47	(49.4)	0.14
Pancreatico jejunostomy fistula, n (%)	5	(11.1)	10	(10.5)	0.65
Hepaticojejunostomy fistula, n (%)	3	(6.6)	8	(8.4)	0.23
Gastrojejunostomy hemorrhage	1	(2.2)	3	(3.1)	0.18
Delayed gastric emptying, n (%)	15	(33.3)	34	(35.7)	0.62
Intraperitoneal hemorrhage, n (%)	3	(6.6)	7	(7.3)	0.81
Pancreatic stump pancreatitis, n (%)	1	(2.2)	3	(3.1)	0.18
Intraperitoneal abscess	2	(4.4)	5	(5.2)	0.65
Wound infection, n (%)	4	(8.8)	10	(10.5)	0.42
Other, n (%)	5	(11.1)	12	(12.6)	0.71
Re-laparotomy, n (%)	3	(6.6)	6	(6.3)	0.16
Hospital mortality, n (%)	1	(2.2)	3	(3.1)	0.18
Median hospital stay (days)	16	-	15	-	0.93

DISCUSSION

Pancreaticoduodenectomy (PD) is the treatment of choice for some benign and malignant lesions of the pancreatic head, ampulla, duodenum and proximal bile duct and represents the option of curative treatment in cases of malignancy (2). The first description was given by Whipple et al. (10), and although the classical PD surgical technique has undergone several modifications the morbidity remains high, with a rate close to 40% (11). Regionalization of the surgeries to high-volume centers had a great impact in decreasing the mortality rate.

Because of the continuous decline in mortality rate, PD has become nowadays a routinely performed procedure for tumors of the periampullary region and pancreatic head, with or without invasion of the mesenteric-portal axis (12).

Hemorrhage and pancreatic stump is-

sues remains the major concerns in the assessment of postoperative morbidity. Another predicament in performing PD is the complex anatomy of the peripancreatic vasculature (11). Celiac axis and hepatic arterial variants have been reported in 49% of the patients with pancreatic or hepatobiliary neoplasms (3).

Patient particularities (prior surgery, obesity, enlarged lymph nodes or a biliary stent) can determine difficulties for the accurate intraoperative evaluation of an aberrant hepatic artery.

Variations in hepatic arterial anatomy in the general population are estimated to range from 21 to 49% (4, 11). The most frequently described abnormality is the right hepatic artery arising from the superior mesenteric artery, with an incidence of up to 29% (4, 6). In our series, the distribution of has been of 22 aberrant RHA, 16 accessory RHA, 1 common HA arising from SMA, 2 cases of rRHA and a LHA, and 1 accRHA associated with LHA.

The embryological explanation for the occurrence of aberrant vessels is based on the quantity of signaling molecules and growth factors involved in normal development of any viscera, resulting that an improper signaling and incorrect gradient in visceral growth can cause abnormalities (13).

Nowadays, CT scans are commonly used for the diagnosis of periampullary tumors and to determine the tumor stage and to assess the resectability (4,14). Multidetector computed tomography with angiography is the best method for detection (14).

The detection of an arterial variant involves a technical difficulty that may determine a more conservative resection of the pancreas, especially for retro pancreatic plane, and occasionally inadequate tumor removal (1). Assessment of hepatic arterial anatomic variants in patients who are about to undergo PD is an imperative procedure, allowing the surgeon to minimize such complications as extensive hepatic injury (hepatic necrosis, ischemic biliary injury or anastomotic complications) (11, 15). It is well known that the vasculature of the cranial part of the bile duct is dependent on the right hepatic artery and sparing it is crucial in limiting a breakdown of bilioenteric anastomosis despite the existence of a hiliar vascularization (16)

Is important to recognize a vascular lesion and to proceed to revascularization if there is simultaneously an aberrant right hepatic artery, an accessory RHA with a high flow to the right lobe or an aberrant common hepatic artery (1, 9, 16) Several techniques have been described for RHA reconstruction in case of tumor infiltration or when the intraparenchymal course does not ensure an R0 resection (15, 16). In the literature techniques using interposition of a vein or prosthetic graft have been described (16).

In our study, we found a slight but statistically insignificant increase in surgery duration in the HAav group. No group differences were also found in the amount of packed red blood cells transfused intraoperatively. Bleeding and complication rates were similar in our two groups, findings supported by other studies. The posterior approaches allowed an early control of the retro pancreatic vasculature with more accurate hemostasis in case of bleeding lesions (pancreatic pseudo aneurysm), early assessment of resectability, and sparing of an aberrant hepatic artery originating from the superior mesenteric artery (11).

CONCLUSIONS

A good preoperative assessment of hepatic artery variants allows surgeons to perform the PD in conditions of safety, preventing liver damage and a higher rate of complications like performing the surgical procedure in patients with standard anatomic hepatic arterial disposition. Further prospective studies are required to determine the best surgical approach in cases of aberrant hepatic artery disposition, since there is no worldwide consensus.

A THIN AND REGULAR ENDOMETRIUM IN ENDOMETRIAL CANCER-ENDOVAGINAL ULTRASOUND ASSESSMENT (Abstract): **Aim**: Our study had as a major objective the highlighting of more objective criteria in establishing the morphological diagnosis and the evaluation of prognosis elements in endometrial hyperplasia and endometrial carcinoma, representing a specific pathology for the premenopausal and postmenopausal women. Endometrial adenocarcinoma is a malignant tumor, rare in women under 40 years of age, but the incidence increases after menopause, gradually reaching a maximum between 70-79 years. **Material and methods**: The study included 291 patients with endometrial adenocarcinoma. The patients were admitted in 2005-2010 to "Cuza-Voda" Obstetrics and Gynecology Hospital in Iasi. The study group was diagnosed and investigated on the basis of the clinical examination and the specialized complementary explorations. The histopathological diagnosis was obtained by the processing of the hysterectomy specimen. **Results**: The results of the study that we conducted highlight the fact that nearly half of the patients diagnosed with endometrial adenocarcinoma were 50-59 years old. In 78.01% cases the uterus was of normal size, between 4-6cm, in 10.31% cases was increased over 6 cm and 11.68% it was of small size, less than 4 cm. **Conclusions**: The study recommends surveillance of cases with endometrial hyperplasia especially if are associated with incriminated risk factors in the etiology of carcinoma of the uterus.
Keywords: ADENOCARCINOMA, ENDOMETRIUM, ULTRASONOGRAPHY.

In the current gynecological practice there are many uterine lesions, many of which may be associated with abnormal uterine bleeding, and for this reason they should be excluded before diagnosing a dysfunctional uterine bleeding. In pre- and postmenopausal women, the most frequent morphological substrate of abnormal uterine bleeding is the hyperplasia of the endometrium and the endometrial carcinoma (1)

The noninvasive diagnosis of such bleeding can be done through endometrial cytology, endovaginal ultrasound and tumor markers (2).

The endometrial cytology has limited value because it is an indirect method, the results of which are encumbered on the one hand by false-negative results due to the

fact that the malignant endometrial cells rarely exfoliate spontaneously and if such phenomenon occurs, they undergo a number of changes during the passage through the genital tract. If endometrial cytology is sampled directly with a brush or by washing, the results are more precise (3).

The tumor marker is not specific to the endometrial carcinoma - CA 125 and, in the early phase of the disease, it is not increased so it did not constitute a diagnostic indication (4).

The endovaginal ultrasound (EEV) is currently accessible, non-invasive and painless and it is used frequently in the screening, assessment and monitoring of metrorrhagia in pre- and postmenopausal women (5).

Endometrial adenocarcinoma is a malignant tumor, rare in the Caucasian women under 40 years of age, but the incidence increases after menopause, gradually reaching a maximum between 70-79 years. The women of the black race, the maximum incidence of the endometrial adenocarcinoma is reported in premenopausal, with a rate of 85 cases per 100,000 women annually.

EH is considered to have increased risk of endometrial carcinoma. It is a common condition and it includes a wide spectrum of histological changes, from the simple aggregation of glandular proliferation with normal appearance, to changes difficult to distinguish from endometrial carcinoma. The EH diagnosis raises three issues: the first relates to the reproducibility of less than 50% between observers; the second is the finding that around 50% of the cases with atypical hyperplasia (AH) have also carcinoma lesions, and the third stems from the fact that the data about the progressive risk of evolution of EH towards the endometrial carcinoma are limited. Current data shows that, in the long term, the risk of developing endometrial carcinoma is less than 5% for women with simple hyperplasia (SH) or complex hyperplasia (CH) but it is of up to 30% for those with atypical hyperplasia (AH).

MATERIAL AND METHODS

Endometrial adenocarcinoma is a malignant tumor, rare in women under 40 years of age, but the incidence increases after menopause, gradually reaching a maximum between 70-79 years.

The study included 291 patients with endometrial adenocarcinoma. The patients were admitted in 2005-2010 to "Cuza-Voda" Obstetrics and Gynecology Hospital in Iasi. The study group was diagnosed and investigated on the basis of the clinical examination and the specialized complementary explorations. The histopathological diagnosis was obtained by the processing of the hysterectomy specimen. We used the data recorded in the observation charts and the computerized system.

The data collected as a study material and considered refer to: the total number of cases of endometrial carcinoma, diagnosed and operated, the annual distribution of the cases, the repartition of cases according the age groups, the type of the invasion of the tumor tissue myometrium, distribution of cases according to the length of the uterine cavity.

Even though the number of cases hospitalized and operated on different gynecological diseases was on the rise at our hospital between 2005-2010, this was not seen in the case of endometrial adenocarcinoma. The maximum number of cases was, at the beginning of the study, years 2005-2007 (96 cases), 2,87% of the surgeries during that period.

In the studied cases, the results of the endovaginal ultrasound exam are relevant.

For the 291 patients with endometrial carcinoma, the local vaginal exam combined with the abdominal palpation and correlated with the endovaginal ultrasound established the size and thickness of the endometrium of the uterus.

Our study, consisting of the two groups of endometrial adenocarcinoma, shows that between the endometrioid and the non-endometrioid adenocarcinoma there are significant differences regarding the invasion in the myometrium.

RESULTS

Of the total number of patients included in the study, 25% are between 33 and 53 years old, and 50 % are up to 58 years old. Most cases of endometrial adenocarcinoma, in our study, have been reported in patients aged 53 (modal or dominant value).

The results of the study that we conducted highlight the fact that nearly half of the patients diagnosed with endometrial adenocarcinoma were 50-59 years old. Among the 291 patients, 268 (92.1% of the total) were postmenopausal.

In the study that we conducted, the diagnosis of admission was neoplasm of uterine body in 197 (67.7%), endometrial polyp in 6 (2.06%), uterine fibroid in 59 (20.27%) and hemorrhages in peri climax in 29 (9.97%).

Another important factor of the prognosis for the patients with endometrial adenocarcinoma refers to the invasion of the tumor tissue myometrium.

Among the 291 studied cases, in 9 patients (3,09%) the tumor tissue has not infiltrated the myometrium; in 148 (50,85%) the myometrium has been infiltrated in a proportion of not less than 50% (the infiltration was limited to the internal half of the myometrium), while in 134 (46,06%) the myometrium showed a tumor infiltration of more than 50% cases.

The results obtained in our study reveal that over half of the cases showed evidence of the presence of lymphatic invasion in the vessel-lymphatic area (157; 53.95% of the studied cases). By age groups, the invasion of the vessel-lymphatic area was at its maximum for the patients falling in the range of 50-54 years (43; 14.78% of the patients included in the study).

Depending on the distribution of the endometrial adenocarcinoma according to the length of the uterine cavity in over 60% of the cases, the uterine cavity size was over 4 cm, and in a quarter of cases studied by us it was of 4 cm. Uterine cavity has a normal length of between 3-5 cm. In the cases included in the study, the uterine cavity length, assessed according to the hysterectomy specimen, was in average 5.019 ± 1.494 cm. Most often we found a value of 4 cm of length of the uterine cavity, but the limits of variation for the studied cases were very high. Therefore, the smallest length recorded was 2 cm, and the maximum recorded value was of 14 cm.

In our study, from the 291 cases of endometrial adenocarcinoma, in 205 (70.44%) by way of ultrasound it was reported the coexistence of hypertrophic or athrophic changes of the endometrium. Adenocarcinoma cases were included in two groups, the first group having 43 patients (20.98%) with endometrial adenocarcinomas associated with hypertrophy that histologically have proven to be hyperplasia and the second group represented by 162 (79.02%) with adenocarcinoma developed onto an atrophic endometrium.

In 86 (29.55%) cases there was not any ultrasound identification of hypertrophic or atrophic aspects of the endometrium.

The histopathological diagnosis was specified on histological sections taken

from the pieces of the surgical resection. In all cases the histological grading was established, along with the invasion of the myometrium.

The value of the endovaginal ultrasound in the diagnosis of the endometrial carcinomas is relevant. Depending on the size, the size of the uterus was divided into three categories: normal size, reduced size and increased volume. The size of the uterus was established following a clinical exam correlated to the endovaginal ultrasound. (fig. 1).

In 227 (78.01%) of the cases the uterus was of normal size, between 4-6 cm; in 30 (10.31%) cases its volume was increased, over 6 cm, and in 34 (11.68%) cases it was of small size, less than 4 cm.

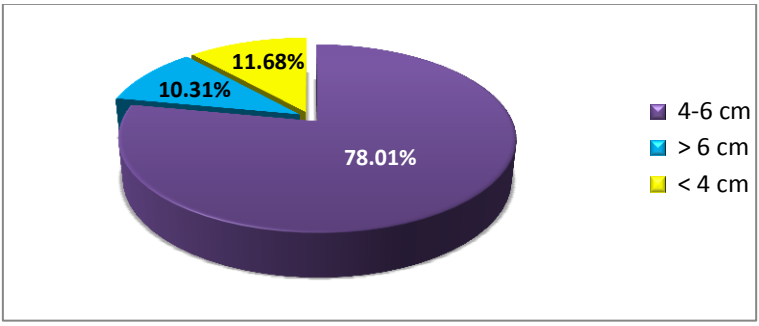

Fig. 1. Distribution of cases depending on the size of the uterus

The total thickness of the endometrium has been measured in the sagittal plan, endovaginal, including any area of focal thickening. The presence of areas with high echogenity, which interrupted the normal trilaminar structure of the endometrium pointed out to an endometrial pathology (fig. 2).

Fig. 2. Endometrium thickness determined by endovaginal ultrasound

In 275 (94.50 %) patients with endometrial carcinoma from our study, the endometrium thickness determined by endovaginal ultrasound was averaging 15 mm, with limits between 5 and 65 mm. In 16 (5.5%) patients with endometrial carcinoma, the

endometrium thickness determined by endovaginal ultrasound was under 5 mm, with limits between 5 and 4.5 mm (fig. 3).

In the case of patients with endometrium thickness under 5 mm, studying the observation sheets, the anamnesis (clinical history and menstrual status) revealed that in the last 3 months, prior to admission, these patients have undergone uterine cavity curettage, that all the patients were between 60 and 69 years old, they were in postmenopausal, and the histopathological examination has identified different types of endometrial carcinoma.

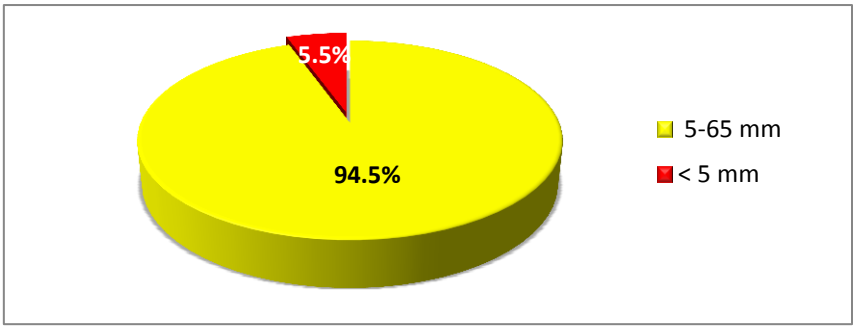

Fig. 3. Distribution of cases depending on the size of the endometrium

DISCUSSION

From the clinical and ultrasound study of 291 endometrial adenocarcinomas, there are a few issues that need to be highlighted and discussed in the light of the recent data from the medical literature.

Our study proves that endometrial hyperplasia are a common diagnosis in pre- and postmenopausal patients, they are often identified as a result of investigations for abnormal uterine bleeding; these are issues that should be considered by the gynecologist during the routine consultations and it is subsequently required an endovaginal ultrasound for the assessment of the thickness of the endometrium.

Most authors (6) consider that measuring the thickness of the endometrium through the EEV is a method with high specificity for the diagnosis of the endometrial carcinoma, especially in postmenopausal women. According to the results in the literature (7), the normal limit thickness of endometrium in postmenopausal women is 5 mm, and above it the endometrium biopsy with histopathological interpretation is required, but some results concerning the linking of the over 5 mm thickness of the endometrium to EEV with severe endometrial pathology would be of only 4% (8). Studies on the histology of a 6 mm thick endometrium at EEV showed a specificity of 98%, but a sensitivity of only 17% which leads to the conclusion that EEV is not an appropriate method for the screening of the endometrial carcinoma (9). Another study published results showing that using for EEV a limit value of 4 mm thickness of endometrium in women with postmenopausal bleeding both for those who used hormonal substitute treatment (estrogen and progesterone) and those without such treatment, the sensitivity in detecting the endometrial carcinoma was 100% and the specificity of 60% (10).

Normal endometrium has a thickness of under 5 mm in postmenopausal women and its borders must be regular and visible throughout the uterine cavity. For the interpretation of the thickness of the endometri-

um, in our statistics (10) we took into account the literature data, which show that the endometrium with a thickness greater than 5 mm in postmenopausal women is associated with an increased probability of the existence of a hyperplasia or an endometrial carcinoma, and any focal lesion of the endometrium, revealed at endovaginal ultrasound, regardless of the thickness of the endometrium, requires endometrial biopsy.

Our results confirm the data from the literature (11), showing that the endometrial adenocarcinoma in postmenopausal patients can be associated with a thin endometrium, with a thickness under 5 mm.

However, such cases published in the literature are rare. Thus, until 2007, founds in the literature only 14 authors who reported cases of endometrial adenocarcinoma in postmenopausal patients, where the endovaginal ultrasound showed a thickness of under 5 mm of the endometrium (12,13).

With the help of the endovaginal ultrasound with pulsed Doppler it is identified, highly accurately, the presence of the endometrial adenocarcinoma, which determines the decrease of the number of false-positive results (14).

The studies published in the literature specify that tumor infiltration in the myometrium is associated with a poor prognosis. Adenocarcinomas limited only to the endometrial mucosa have a survival rate of over 95% at 5 years (15).

CONCLUSIONS

Our study revealed that the endovaginal ultrasound assessment of the thickness of endometrium, is absolutely necessary in the diagnosis of the endometrial lesions and it has an important role in the screening of endometrial adenocarcinoma. The endovaginal ultrasound can provide orientation in more than 90% of the cases, the existence of a proliferative lesion of the endometrium in postmenopausal women, where the thickness of the endometrium is greater than 5 mm.

Also, our study had as a major objective the highlighting of more objective criteria in establishing the morphological diagnosis and the evaluation of prognosis elements in endometrial hyperplasia and endometrial carcinoma, representing a specific pathology for the premenopausal and postmenopausal women.

If the endovaginal ultrasound reveals the endometrium with a thickness of less than 5 mm and regular layout, in patients that are in pre- and postmenopausal at increased risk and abnormal uterine bleeding, who underwent a previous biopsy, within a period of less than three months from the date of the first submission, the uterine curettage is necessary for a more accurate histological diagnosis.

NEWS

PERFORMANCE OF MOLECULAR TESTS IN THE DETECTION OF *TRICHOPHYTON* SPECIES

Dermatophytosis caused by *Trichophyton* and *Microsporum* species represent the most frequent mycoses worldwide. Molecular detection methods are highly sensitive and allow for rapid and accurate identification of dermatophytes from clinical specimens. Kupsch *et al* investigated the sensitivity of different molecular methods compared with conventional diagnostics (culture) in the detection of dermatophytoses caused by *T. rubrum* and *T. interdigitale* in 375 clinical samples of nail, skin and hair. The compared molecular methods included already published PCR-ELISA assays, qRT-PCR as well as a newly developed PCR-ELISA targeting the internal transcribed spacer region. In 39.5 % of cases a positive result was obtained in at least one molecular test or by culture. The results shoed that the most sensitive test was a PCR-ELISA targeting a microsatellite region which identified 81 *T. rubrum*-infections followed by an ITS PCR-ELISA (60), qRT-PCR (52) and a topoisomerase II PCR-ELISA assay (51); significantly, cultivation detected *T. rubrum* in only 37 samples (Kupsch C, Ohst T, Pankewitz F, Nenoff P, Uhrlaß S, Winter I, et al. The agony of choice in dermatophyte diagnostics - Performance of different molecular tests and culture in the detection of *T. rubrum* and *T. interdigitale*. Clin Microbiol Infect. 2016 May 30. pii: S1198-743X(16)30142-2. doi: 10.1016/j.cmi.2016.05.015).

INFLUENCE OF GLAUCOMA ON DIABETES-INDUCED CHANGES IN THE ANTERIOR OCULAR SEGMENT (Abstract). **Aim**: To monitor the influence of glaucoma on the changes caused by diabetes in the anterior ocular segment. **Material and methods**: Prospective, comparative clinical study, which included the patients with glaucoma and diabetes assessed at the Iaşi "Sf. Spiridon" Hospital, "Euro Medi Center" Clinic and "Oftaprof" Clinic. The study included a number of 142 patients, divided into two groups: 67 patients with glaucoma and diabetes (study group) and 75 patients with diabetes mellitus (control group). Upon enrollment the patients were subjected to a complete assessment of their ophthalmologic and metabolic status. Monitored aspects: prevalence of lens changes, extent of ocular surface disease and identification of the changes in corneal biomechanical parameters in the patients with glaucoma and diabetes. **Results**: In both monitored groups, the cortical lens changes prevailed, both at the beginning and at the end of the study, with no statistically significant differences between groups ($p>0.05$). The risk of developing lens changes reaches 50% in the patients who have had diabetes for 20 years. In the patients in the study group, tear secretion was significantly lower at the end of the study (Schirmer's test values 11.61 vs. 10.67 mm, $p=0.045$). Tear film instability was present in 37.3% of the patients. Corneal hysteresis (CH) and corneal resistance factor were significantly reduced in the group with glaucoma and diabetes, as compared to the group with diabetes ($p=0.001$). **Conclusions**: There is significant ocular surface disease in the patients with glaucoma and diabetes, as compared to those with diabetes alone. Glaucoma and the number of antiglaucoma drugs are associated with a significant reduction in tear secretion. The association of glaucoma resulted in the reduction in CH and corneal resistance factor in the patients with glaucoma and diabetes as compared to the healthy ones. **Keywords**: POAG, CH, CRF, SCHIRMER'S TEST, OSDI QUESTIONNAIRE.

Diabetes and glaucoma are two chronic conditions with a significant impact on visual function, both determining degenerative changes at ocular level. In the patients with diabetes and in those with glaucoma, the vascular factor has an important role, in both conditions abnormalities in retrobulbar vascular flow and retinal microcirculation being present (1). These are a problem mainly in the developed countries with high life expectancy. Most complications involve both the anterior and the posterior segment of the eye, but numerous clinical studies only describe the presence of changes caused by diabetic retinopathy. A range of other ocular changes at the level of the lens and cornea are not well documented and that this study aims to highlight them (2). Studies in the

literature have shown that lens changes are a cause of severe visual impairment in diabetic patients, the most frequent changes occurring at cortical and posterior subcapsular level, the risk increasing with diabetes duration and poor glycemic control (3,4). Ocular surface changes associated with diabetes have been carefully studied over the last decades. Clinical studies have shown that diabetes is associated with lacrimal gland dysfunctions, reduction in reflex tear secretion and tear film break-up time of the (5,6). Other studies aimed to demonstrate the role of diabetes and glaucoma in the changes in ocular biomechanical parameters, mostly with contradictory results. It was found that these properties determined by ORA (Ocular Response Analyzer) are affected by glucose level, hyperglycemia determining dysfunctions of the corneal endothelium (7,8,9). This study aimed to assess the influence of glaucoma on the diabetes-induced ocular changes in the anterior segment (lens, ocular surface, corneal biomechanics).

MATERIAL AND METHODS

This is a prospective, observational and comparative clinical study carried out in the Ophthalmology Clinic I of the Iaşi "Sf. Spiridon" Hospital in collaboration with the "Euro Medi Center" and "Oftaprof" Clinics. The study was carried out in accordance with the ethical principles of the Declaration of Helsinki, the protocol being explained in detail to each patient, and obtaining the informed consent for the participation in the study. *The inclusion criteria* were: age over 35 years, confirmed diagnosis of primary open-angle glaucoma (POAG) and normal-tension glaucoma (NTG), open camerular angle (III-rd, IV-th degrees) according to Schaffer's classification, associated mixed type 1/type 2 diabetes, assessed based on blood sugar and glycosylated hemoglobin levels. *The exclusion criteria were:* patients with very advanced glaucoma, secondary glaucoma (pseudoexfoliative, pigmentary, neovascular, cortisone-induced), absence of DM and patients not attending the subsequent checkups. The participants were therefore divided into two groups: study group (including patients with glaucoma and diabetes) and control group (patients with diabetes). After enrollment the patients were assessed every 3-6 months.

The protocol for patient assessment included a comprehensive eye and vision examination: visual acuity, intraocular pressure (IOP) measured by Goldmann aplanotonometry, biomicroscopy of the anterior segment, central corneal thickness (Tomey ultrasound pachymeter), computerized recording of visual field by using the glaucoma programs of Humphrey perimeter, indirect gonioscopy with Goldmann three mirror lens, eye fundus exam with Volk lens and retinal photography with Zeiss Fundus Camera. The identification of changes in the retinal nerve fiber layers and the C/D (cup/disc) ratio were carried out by using the Zeiss Cirrus HD OCT device. Lens status after pupil dilation was assessed by biomicroscopy of the anterior segment and by photographic documentation using a Topcon biomicroscope provided with a digital camera, three images being obtained per eye and the type and extension of lens opacity was recorded using as a rough guide the LOCS (Lens Opacities Classification System), the most frequently used system in clinical studies. Both upon enrollment and at the end of the study, every study patient was subjected to Schirmer I test (without anesthesia), BUT (break-up time) and to fluorescein staining. At the end of the follow-up period, the patients filled in an OSDI (Ocular Surface

Disease Index) questionnaire, used to obtain various aspects related to the ocular surface disease. The OSDI includes 3 subscales: ocular discomfort (5 questions), ocular symptoms during daily activities (4 questions) and environmental factors (5 questions); the OSDI total score is assessed on a scale of 0 to 100: 0-12 normal, 13-22 moderate, 33-100 severe. By means of the ORA (Ocular Response Analyzer), the corneal biomechanical parameters have been assessed: CH, corneal resistance factor (CRF), IOPcc (corneal-compensated intraocular pressure) and IOPg (Goldmann- correlated intraocular pressure). Diabetes was assessed by determining the serum level of blood sugar and glycosylated hemoglobin (HgA1c). Diabetes and glaucoma duration and the number of antiglaucoma drugs were noted. The statistical analysis of the data was performed by using the SPSS 18.0 statistics software. Of the used statistical tests, we mention: the ANOVA test, t student (statistically significant at $p<0.05$), chi^2 test, Pearson correlation, Krushall –Wallis correlation, ROC curve (prognostic factor) and the Kaplan –Meier curve (probability, hazard).

RESULTS

The study group included 142 patients with DM, divided into two groups: group I - 67 patients (47%) with diabetes and POAG and group II (controls) - 75 diabetic patients (53%) without glaucoma. The statistical analysis utilized data from one eye only, the most affected one. Gender distribution showed a prevalence of females in both groups. Mean age was 65.58+/- 7.87 years, the groups being homogenous in this respect. Diabetes duration was of 11.01+/- 8.28 years in group I and 13.32+/-9.94 years in group II. Glaucoma duration was of 5.75+/- 4.54 years. According to Hodapp classification, depending on the Mean Deviation level, the patients in group I presented moderate glaucoma both at the beginning and at the end of the study. Only one case was classified as advanced glaucoma (MD> -12db) and was not taken into account in the final evaluation. Of the total number of patients, 22.38% had NTG and 77.62% POAG. At the beginning of the study we found that 68.7% of patients in group I and 57.3% of patients in group II had statistically significant cortical lens changes ($p=0.036$). The other changes (subcapsular, nuclear, corticonuclear) were present in much lower percentages (12%, and 14.7%, respectively).

At the end of the study, in both groups, the percentage of cortical lens changes had decreased, but there was an increase in the percentage of cortical nuclear opacities, the changes at nuclear level determining cataract worsening and impaired visual function (fig. 1).

In the studied cases, multiple linear regression analysis revealed that gender, age, diabetes and glaucoma duration are not good predictors of lens changes ($p>0.05$), a positive cumulative correlation being found in only 3.4% of the patients. At the end of the study the glycosylated hemoglobin level was significantly lower in the patients with cortical changes both in group I (7.03 vs. 6.61%, $p=0.02$) and in group II (7.30 vs. 6.91%, $p=0.025$). Kaplan Meier curve highlighted an increased risk of developing lens changes, more than double in patients suffering from diabetes mellitus for almost 20 years. The probability of developing lens changes reaches the level of 50% in the patients suffering from diabetes mellitus for 10 years or from primitive open-angle glaucoma for 5 years (fig 2).

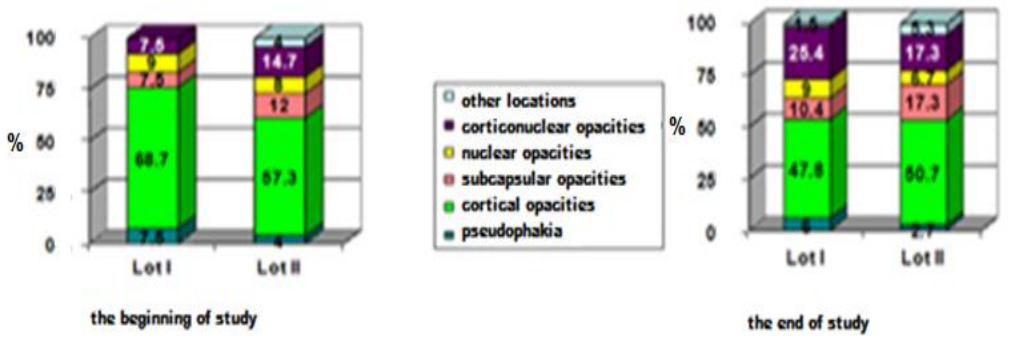

Fig. 1. Group structure according to lens modifications at the beginning and at the end of the study (Group I=glaucoma and diabetes; Group II=diabetes)

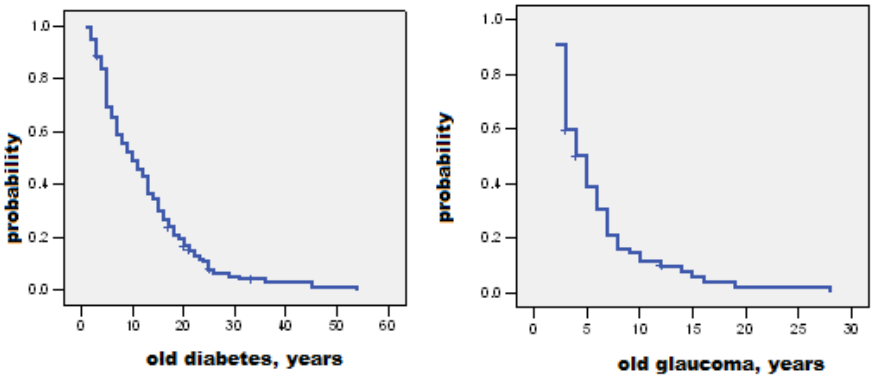

Fig. 2. Probability of lens changes depending on diabetes and/or glaucoma duration

Tear secretion test (basal Schirmer's test) values ranged from 3 to 25mm, a severe value (3 mm) being recorded in one patient (0.7%) low tear secretion values (5-10mm) in 35 patients (26.4%). The average values of Schirmer's test had significantly decreased towards the end of the study in the group I patients (11.61 vs. 10.67; p=0.045) as compared to group II. Tear film break-up time (BUT) ranged from 3 to 21 seconds, tear film instability being recorded in 37.3% of the patients (fig. 3). The ocular surface disease index (OSDI) ranged from 8.33 to 39.58, highlighting a severe damage in 6% of the cases and moderate in 16.4%. Similarly, to tear secretion, in group I patients there was a significant decrease in BUT (9.33 vs. 8.57, p=0.028), but without significant differences in group II, the control group.

The number of glaucoma drugs ranged from 1 to 3. There was an association of 2, 3 drugs in 40% of the patients in the study group. At the end of the study, tear secretion test revealed significantly lower values in those on 3 or more glaucoma drugs (p=0.037). In case of BUT and OSDI there were no statistically significant differences according to the number of glaucoma drugs. The multivariate analysis highlights that Schirmer's test, BUT, OSDI questionnaire and the IOP level are good predictors in the determinism of the degree of ocular damage (p=0.014):

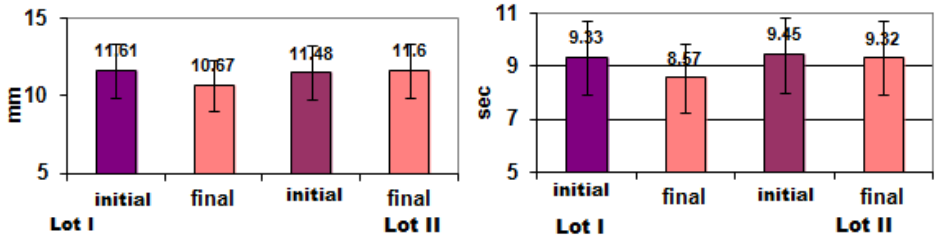

Fig. 3. Average values of the Schirmer's test and BUT by study groups

The assessment of the changes in corneal biomechanical parameters included 156 subjects, 49 subjects with diabetes and glaucoma (90 eyes) selected from group I and 17 subjects with diabetes mellitus (34 eyes) selected from the control group (group III), who were able to be assessed by ORA. These groups of subjects were compared to a group of 46 subjects (92 eyes) with primary open-angle glaucoma (group II) and a group of 48 normal subjects (96 eyes) (group IV). The statistical analysis took into account the measurements in both eyes. Assessment of central corneal thickness (CCT) highlighted no statistically significant differences among the study groups in the right eye (p=0.561) or in the left eye (p=0.455). Goldmann-measured IOP, Goldmann-correlated IOP, corneal-compensated IOP had significantly higher values in groups II and III as compared to group IV (p<0.005), with no differences between the two eyes. Both in the right eye (p=0.001) and in the left eye (p=0.001), CH values were significantly lower in the patients in group I and II, as compared to group IV. The CRF values were significantly lower in the patients with G+/- DM as compared to the other groups (p=0.011), with no statistically significant differences between the two eyes (fig. 4).

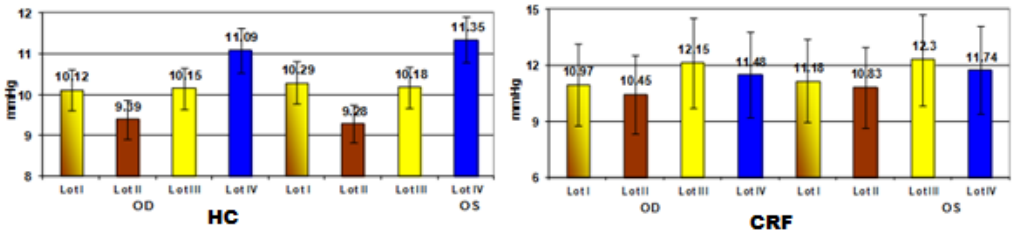

Fig. 4. Average values of corneal hysteresis and corneal resistance factor (mmHg) by study groups (Group I= glaucoma and DM; Group II= glaucoma; Group III=diabetes; Group IV=healthy)

The comparison between CH *and* IOP revealed statistically significant, direct moderate correlations only in group III. The comparison between CH *and* the CCT highlights direct correlations (if the value of the correlation coefficient is closer to +1 there is an all the higher dependence of the two parameters, direct correlation, and if closer to -1, it shows that there is also a very high dependence between the parameters, but an indirect one) with moderate intensity, statistically significant in all groups (r=+1,

$p<0.05$). The comparison between CRF and Goldmann-measured IOP shows that there is a direct, moderate, statistically significant correlation in group II only ($r=+0.579$, $p=0.001$). Moreover, the comparison of CRF and CCT values shows direct, moderate, statistically significant correlations in groups I, II, IV ($r=+1$, $p<0.05$) and indirect correlations in group III ($r=-1$, $p<0.05$). In the diabetic patients with POAG (group I) as compared to those without POAG (group II), we noticed significantly lower values of IOP measured by the Goldmann tonometer and of CRF in both eyes. The level of glycosylated hemoglobin did not significantly influence the values of corneal biomechanical parameters in any of the groups ($p>0.05$). The multivariate linear analysis highlights age, CCT, CH and CRF as good predictors in the determinism of glaucoma+/- diabetes mellitus.

DISCUSSION

The common epidemiological and pathogenic features, the complications involving the ocular structures with irreversible effect on vision have determined the serious assessment of diabetes and glaucoma in numerous studies, some of them with contradictory results. The most controversial result is the one of the Ocular Hypertension Treatment Study (OHTS), the authors concluding that diabetes is a protective factor for glaucoma, a low percentage of the monitored patients with diabetes developing glaucoma (3.1%) (10). Other studies find associations between diabetes and glaucoma, suggesting that diabetes is a risk factor for glaucoma (11,12). A retrospective study carried out on 46 patients with glaucoma and diabetes (92 eyes), highlighted a (marginal statistically) significant influence of the presence of non-proliferative diabetic retinopathy in glaucoma progression (13). This risk is explained by the vascular factor, as the long evolution of diabetes can compromise the vascular, glial and retinal neuronal elements, being associated to a high risk in the development and progression of primary open-angle glaucoma (14, 15). However, most of the studies in the literature only assess the role of diabetes in developing glaucoma; to our knowledge, there are no studies assessing the risk caused by glaucoma on the frequent changes induced by diabetes at ocular level. Knowing that diabetic retinopathy and cataract are the most frequent causes of visual impairment and decreased quality of life in the patients with diabetes, glaucoma association could additionally influence the progression of these changes. The studies in literature have shown that lens changes have an increased prevalence in diabetics (3,4). The results of this study are mostly similar to those in the literature. The groups were homogenous in terms of age (65), the female gender prevailed, the average diabetes duration was of 11 years and of the glaucoma of 5 years. The statistical analysis of the studied cases showed an increased prevalence of cortical lens changes over the study period (68.7% in group 1 and 57.3% in group 2) with statistically significant differences between groups ($p<0.05$). These changes seem to be rather related to diabetes (average duration - 11 years), but they can also be related to age (average age: 65). There were no statistically significant differences between the analyzed groups; therefore, glaucoma did not significantly influence the results. The assessment of ocular surface disease showed a significant degree of ocular surface disease in the patients with G+DM vs. those with DM alone, tear secretion and

tear film break-up time being significantly lower at the end of the study. Glaucoma and the number of glaucoma drugs were associated with a significant decrease in tear secretion (p=0.037). Schirmer's test, BUT, OSDI questionnaire proved to be good predictors of the degree of ocular involvement. Similarly to the studies in the literature comparing the degree of ocular surface disease in patients with glaucoma as compared to those without glaucoma, we found a higher degree of ocular damage due mostly to glaucoma therapy (2,16). The studies in literature assessing the biomechanical properties in patients with diabetes report controversial results. Some studies state that diabetes causes a CH decrease as compared to healthy subjects, others that CH and CRF are significantly increased in patients with poor blood sugar control, as compared to the healthy subjects with good control (8,9,17). CH decrease is explained by the alteration of collagen components, thus reducing the corneal dumping phenomenon, and CH increase is due to the rigidity of collagen structure of the cornea in diabetics (20). The reasons for such contradictory results are probably the differences in age and CCT, but also the diversity of DM types and their severity (in some studies most patients had type 2 diabetes, while others had a similar number of patients with type 1 and 2 diabetes). Similarly, the results obtained in our study show that glaucoma association determined a reduction of CH in the diabetics with glaucoma as compared to those without glaucoma and healthy control subjects. This is explained by the known fact that in glaucoma there is a reduction in corneal viscosity and corneal dumping phenomenon. The altered collagen structure may be additive to the effect of a thicker cornea, thereby further increasing the measured IOP, which can lead to an overestimation of the true IOP with Goldmann aplanotonometer in the population with diabetes (17).

The present study has some limitations. The obtained results cannot be extrapolated to global level mainly because of the small number of patients included in the study and of the short monitoring period. The absence of a comparative OSDI (ocular surface disease index) score in the group with DM is another limitation. In the groups assessed for changes in corneal biomechanical parameters, there are no data regarding the level of HgA1c, blood sugar upon enrollment and at the end of the study, and degree of glaucoma in the control groups.

CONCLUSIONS

In our study the cortical lens changes prevailed at the beginning of the study in both groups. The probability to develop lens changes is of 50% in the patients with 10-year duration of DM or 5-year duration of the POAG. There was a significant degree of ocular surface disease in the patients with G+DM as compared to those with DM alone. The presence of glaucoma and the number of glaucoma medications are associated with a significant decrease in tear secretion (p=0.037). The association of glaucoma determined a decrease in CH and CRF corneal biomechanical parameters in the diabetic patients with glaucoma as compared to those without glaucoma and healthy control subjects. Age, CCT, CH, CRF and Goldmann- measured IOP are good predictors in the determinism of glaucoma +/- diabetes. In the future, a longer monitoring period and database extension could lead to the improvement of the results obtained in this study.

TREATMENT OF PUBIC DISJUNCTION IN YOUNG-BURGUESS TYPE II AND III PELVIC RING FRACTURES **(**Abstract). **Aim:** To present the personal experience in assessing the treatment of pubic disjunction in Young-Burguess type II and III pelvic ring fractures. **Material and methods**: Included in the study were 30 patients with type II and III pelvic ring fractures, aged 32 to 76 years. Of these, 18 patients were treated with external fixation, and 12 patients were treated surgically: type II fractures were treated with open reduction and internal fixation (ORIF) of pubic disjunction and type III fractures underwent additionally posterior fixation**. Results**: Mean follow-up was 1.6 years. After external fixation we found the persistence of diastasis (1.5 to 4 cm), which was asymptomatic in all cases. Complications included implant failure in 3 patients, and postoperative infection in 2 patients. Among the 5 patients with type II lesions the clinical and radiological scores were excellent in 3, good in 1, and poor in 1. Among the patients with type III lesions the clinical outcomes were excellent in 5 and good in 2. **Conclusions**: External fixation has proved a good treatment option for patients who cannot tolerate a more extensive surgery. There is no conclusive clinical evidence favoring the use of two perpendicular plates vs. 1 plate for pubic symphysis fixation. In osteoporotic patients the use of 2 plates is recommended. **Keywords:** PELVIC RING FRACTURE, PUBIC DISJUNCTION, ORIF.

Pubic disjunction result from high-energy trauma, and occurrs in 14 - 20% of pelvic ring fractures (1). They are frequently associated with multiple other lesions, such as blood vessels rupture with massive hemorrhage, this association having a mortality rate of approximately 15-35% (1, 2). The major sources of bleeding are supposed to be the presacral and retroperitoneal blood vessels. (1).

The conservative treatment of these fractures has proved ineffective. An early firm stabilization and anatomic reduction are recommended to decrease mortality and allow early mobilization (3).

To stabilize these fractures several methods are available. External fixators can be used for the temporary stabilization of all types of pelvic ring fractures or for a definitive one in some cases. Anterior internal fixation can be used as a definitive treatment for pubic disjunctions if the sacroiliac ligaments are intact. Anterior internal fixation may be associated with posterior fixation in patients with posterior pelvic ring injuries (especially in APC type

III) to improve overall stability (4).

MATERIAL AND METHODS

In the interval 2008-2014 in the orthopedics and traumatology units of the Iasi "Sf. Spiridon" Emergency County Hospital and Botosani "Mavromati" Emergency County Hospital 30 patients with type II and III pelvic ring fractures, aged between 32 and 81 years (mean age 55 years) were treated. The mechanisms of fracture were: motor vehicle accidents (17: 56,66%), falls from height (10: 33,33%) and 3 (10%) by crush injury (3). The injuries most commonly associated with these fractures were: head trauma, craniofacial trauma, thoracoabdominal trauma, splenic rupture, bladder rupture, lower leg fracture, forearm fracture, fractured clavicle and humerus.

Eighteen patients were treated with external fixation (fig. 1) and 12 patients were treated surgically: type II fractures were treated with ORIF of pubic disjunction and type III fractures underwent additionally posterior fixation. Pubic disjunctions in type II lesions were fixed with one 3.5 mm reconstruction plate and 4 screws (2 cases/16.6%) and with two perpendicular plates (3 cases/25%); those in type III lesions were treated with one 3.5 mm reconstruction plate and 4 screws (3 cases/25%) and two 3.5 mm reconstruction plates (4 cases/33.33%) (fig. 2).

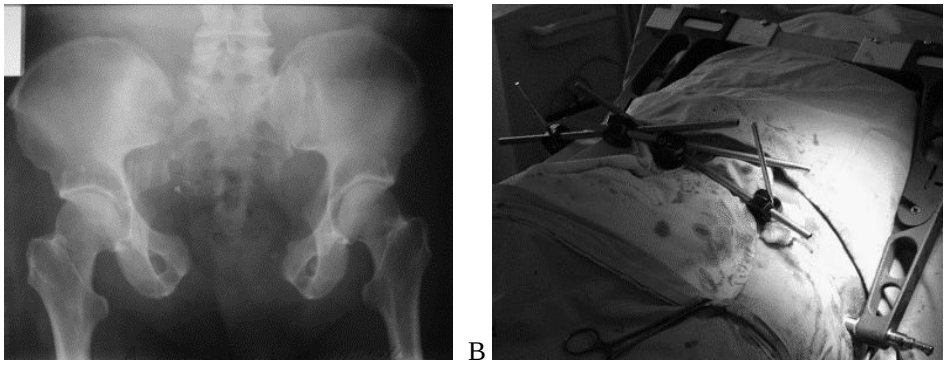

Fig. 1. – patient B.I., 49 years old, victim of motor vehicle accident. A – preoperative X ray – APC type III injury, B – intraoperative view – posterior stabilization with „C clamp" and anterior with supraacetabular external fixation.

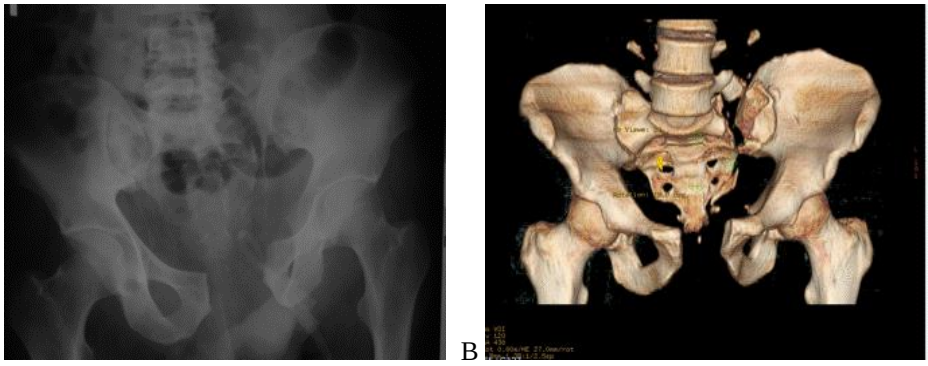

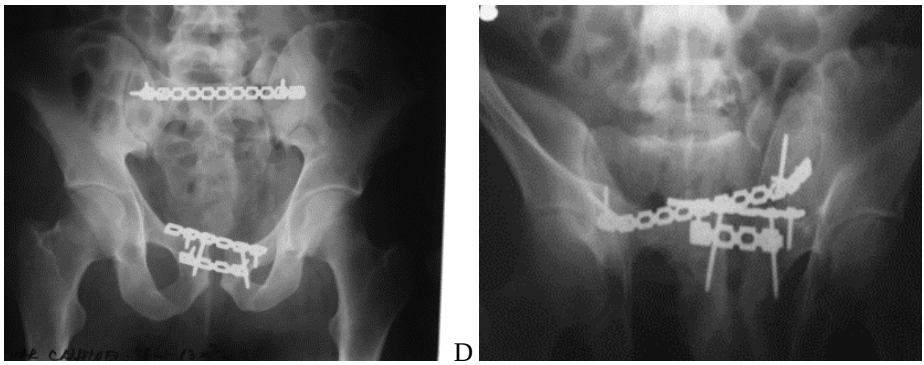

Fig. 2. – patient L.M., 55 years old, victim of motor vehicle accident. A – preoperative X ray – APC type III injury, B – 3D image - APC type III injury, C–postoperative anterior X ray – fixation with 1 plate posteriorly and 2 plates anteriorly, D– postoperative "outlet" X ray – fixation with 1 plate posteriorly and 2 plates anteriorly

RESULTS

Mean follow-up was 1.6 years. The radiologic score and Majeed clinical score were used to assess the outcomes. After external fixation we found the persistence of diastasis (1.5 to 4 cm), which was asymptomatic in all cases (tab.I, II).

TABLE I

Interpretation of the radiologic score

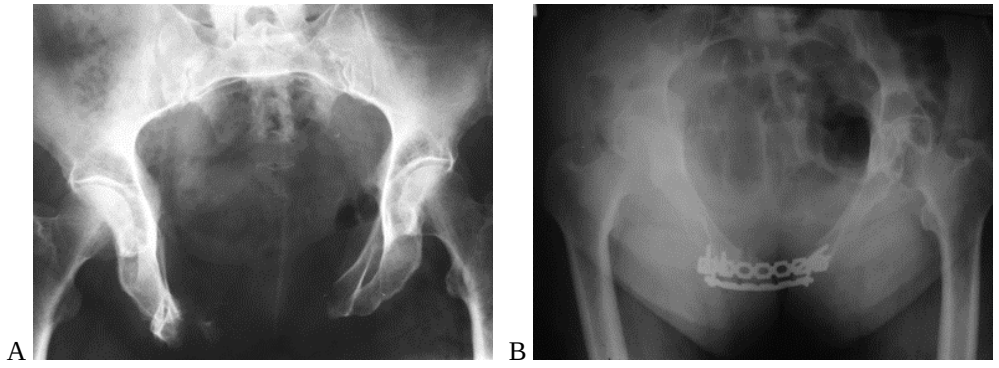
RESULT	RESIDUAL DISPLACEMENT
Excellent	0-5 mm
Good	6-10 mm
Fair	11-15 mm
Poor	>15 mm

TABLE II

Interpretation of the clinical score

RESULT	TOTAL SCORE
Excellent	78-80
Good	70-77
Fair	60-69
Poor	<60

Among the 12 patients treated surgically (ORIF) the complications included construct failure (3:25%) (fig. 3) and postoperative infection (2:16.6%). In the 5 (41,66%) patients with type II lesions, clinical scores were excellent in 3 cases (60%), good in 1 (20%) and poor in 1 (20%).



C  D 
Fig. 3. – patient M.E., 76 years old, victim of motor vehicle accident. A – preoperative X ray – APC type II injury, B – postoperative "inlet" view – fixation with 2 plates anteriorly, C– X ray on postoperative day 7 – loss of reduction, D– postoperative X ray – stabilization with external fixator.

Radiological scores were excellent in 3 (60%) cases, good in 1 (20%), and poor in 1 (20%). Of the patients with type III injuries 5 (71.43%) had excellent clinical outcomes and 2 (28.57%) good. X-ray results were similar to those in type II injuries (tab. III).

TABLE III

Profile of the patients treated surgically by open reduction and internal fixation.

No.	Age	Injury type	Mechanism	Fixation	Radiologic score	Clinical score
1	32	APC II	Vehicle accident [passenger]	Anterior [1 plate]	8 mm	70
2	38	APC III [sacral fracture]	Vehicle accident [motorcyclist]	Anterior [1 plate] + Posterior [1 plate]	5 mm	78
3	61	APC III [sacral fracture]	Vehicle accident [passenger]	Anterior [1 plate]+ Posterior [2 screws]	10 mm	70
4	40	APC III [ligament injury]	Fall from height	Anterior [2 plates] + Posterior [2 screws]	4 mm	77
5	48	APC II	Vehicle accident [passenger]	Anterior [1 plate]	5 mm	80
6	55	APC III [sacral fracture]	Vehicle accident [passenger]	Anterior [2 plates] + Posterior [1 plate]	4 mm	78
7	34	APC II	Vehicle accident [passenger]	Anterior [2 plates]	4 mm	77
8	38	APC II	Vehicle accident [motorcyclist]	Anterior [2 plates]	5 mm	78
9	67	APC III [sacral fracture]	Vehicle accident [pedestrian]	Anterior [1 plate] + Posterior [1 plate]	17 mm	74
10	35	APC III [ligament injury]	Vehicle accident [motorcyclist]	Anterior [2 plates] + Posterior [2 screws]	5 mm	79
11	76	APC II	Vehicle accident [pedestrian]	Anterior [2 plates]	36 mm	56
12	36	APC III [ligament injury]	Fall from height	Anterior [2 plates] + Posterior [1 screw]	5 mm	78

DISCUSSIONS

With the progress made in the emergency care system, prompt diagnosis, resuscitation methods, better management of visceral lesions and improved imaging techniques, the orthopedic surgeon plays a key role in the treatment of these patients (3).

In cases of stable fractures without disjunction and stable ligamentous structures a conservative treatment is accepted with good outcomes. Unstable lesions usually require surgical treatment of the anterior and posterior ring, if the latter is injured (4).

In our study external fixation proved to be a good treatment option for patients who cannot tolerate a more extensive surgery.

Management of APC type II pelvic ring fractures with external fixation is effective, relatively simple, minimally invasive, with less intraoperative blood loss and shorter surgical time and allows earlier patient mobilization (5).

A retrospective study of 64 supraacetabular external fixators to stabilize anterior pelvic ring showed iatrogenic lesion of the lateral femoral cutaneous nerve (4.5%) which reversed within 1 year, no pin site infection, no secondary displacements, perforation of the pin into the small pelvis requiring no treatment in 3% of cases, and pseudoarthrosis of the pubic and ischial rami requiring surgical treatment in 1 case (6). The temporary use of an external fixator is safe and effective, but its use for a definitive treatment is associated with high infection rate and secondary displacements according to the study conducted by Mason (7). Galois L (8) says that anterior inferior placement of the external fixator showed a potential for increased stability.

Pubic disjunctions > 2.5 cm reflect rotational instability and benefit from anterior stabilization, internal fixation being preferred to external fixation. There is no universally accepted protocol on the type of plate (dynamic compression plate *vs.* pelvic reconstruction plate), plate thickness (3.4 *vs.* 4.5 mm) or number of plate screws. There is conflicting evidence on the benefits or need to use a 2-hole plate. It has been agreed that additional posterior instability requires a surgical posterior stabilization procedure (4).

In our surgically treated patients we thought that in case of APC type III injuries anterior and posterior stabilization is mandatory. As to the stabilization of pubic disjunction, no differences between the number of used plates (1 plate *vs* 2 plates) and clinical and radiological scores were found. However, it is worth mentioning that in osteoporotic patients using a single plate does not provide a satisfactory stabilization.

Initially based on biomechanical studies it was considered that adding a second plate can lead to better stabilization, theoretically being indicated in unstable fractures (9).

In a retrospective study Bagchi K. (4) found no conclusive evidence favoring the use of two plates *versus* one plate to stabilize the pubic symphysis. Several clinical and biomechanical studies describe the use of a single plate as appropriate for all types of pelvic ring fractures.

Although plate fixation of pubic disjunctions is the recommended treatment, the incidence and consequences of fixation failure remained a concern. Some of these are due to osteosynthesis material failure and low bone density. However, these do not seem to affect the clinical outcome, because few patients require surgical reintervention (2).

A study evaluating locked versus non-locked plate osteosynthesis of the pubic symphysis showed that locked plates together with the required screws have no advantage over non-locked plates, but further studies are needed (10). On the other hand, Pizanis (11) suggested a biomechanical advantage in using anatomically contoured plates with locking screw capabilities in case of large displacement or obese patients. A biomechanical cadaveric study conducted in 2013 revealed that locked plate osteosynthesis at the pubic symphysis has no advantage over non-locked plates (12).

Lange (13) compared osteosynthesis with a two-hole anterior plate versus two plates (one superior and the other anterior) for pubic disjunction. Double plate osteosynthesis offers a more rigid fixation, but the procedure requires extensive dissection which may cause a significant loss of blood. Single plate osteosynthesis is less rigid and helps accommodate the normal movement of the pubic symphysis without loss of reduction and with a limited dissection.

Simonian (14) and Dujardin (15) in their studies concluded that osteosynthesis of the anterior and posterior pelvic ring is optimal for APC II and III injuries as compared to single plate anterior pelvic ring fixation.

CONCLUSIONS

The results of this study allow us to state that external fixation has proved a good treatment option in patients who cannot tolerate a more extensive surgery. There is no conclusive clinical evidence favoring the use of two perpendicular plates *vs.* 1 plate for pubic symphysis fixation; in osteoporotic patients the use of 2 plates is indicated regardless of lesion type. A residual diastasis below 1 cm is accompanied by good clinical outcomes.

HEART RATE VARIABILITY IN OVERWEIGHT HEALTH CARE STUDENTS: CORRELATION WITH VISCERAL FAT

Overweight and obesity are due to abnormal or excessive fat accumulation that may impair health and it is because of an imbalance between calories consumed and expended. The global epidemic of overweight and obesity is the major public health problem in developed as well as developing world. Abdominal obesity, defined as increased waist circumference is one of the components of the constellation of metabolic abnormalities collectively called as the metabolic syndrome (MS). The latest definition of MS by the International Diabetes Federation (IDF) has included abdominal obesity as one of the essential components. Among the different available non-invasive techniques for assessing the autonomic status, Heart Rate Variability (HRV) is a simple method to evaluate the sympathovagal balance at the sinoatrial level. Increased sympathetic activity, decreased parasympathetic activity and sympathetic imbalance (SVI) has been reported in obese individuals. However, the SVI and its association with visceral fat in overweight health care students have not been explored. Therefore, in the present study, was observed the sympathovagal imbalance due to increased sympathetic activity and its association with visceral fat in overweight individuals (Chintala KK, Krishna BH, Reddy MN. Heart Rate Variability in Overweight Health Care Students: Correlation with Visceral Fat. *Journal of Clinical and Diagnostic Research*. 2015, Vol-9(1): 6-8).

MANIFESTATIONS OF SELF-HARM IN RELATION WITH BINGE DRINKING TO STUDENTS FROM TIMIŞ COUNTY, ROMÂNIA

Iulia Bagiu, Salomeia Putnoky, Ioana Tuță-Sas, Codruța Băcean Miloicov, Mihaela Popa, Brigitha Vlaicu, R. Bagiu

University of Medicine and Pharmacy "Victor Babeş" Timişoara

Corresponding author: E-mail: bagiuiulia@yahoo.com

MANIFESTATIONS OF SELF-HARM IN RELATION WITH BINGE DRINKING TO STUDENTS FROM TIMIŞ COUNTY, ROMÂNIA **(**ABSTRACT): Aim: The research investigated the feeling of sadness, suicidal thoughts and plans associated with binge drinking among students in Timis County, Romania. **Material and methods**: We applied a transversal population study to the representative sample of 2076 students, 62.49% girls and 37.51% boys with a mean age of 21.09 years with SD 1.48. **Results**: The boys practice binge drinking significantly more often than girls, the difference is small to medium: prevalence of 22.1% for boys and 8.7% girls, 1-2 times in the last month. **Conclusions**: Only girls who practice this behavior, increased frequency of engaging in binge drinking is associated with feelings of sadness, suicidal thoughts and suicide plans in a small measure, but significant.
Keywords: STUDENTS, BINGE DRINKING, SELF-HARM.

Binge drinking, the consumption of increased amounts of alcohol on one occasion, typically at age teenager and young adult, has exclusively negative effects on health depending on the amount and frequency of practicing this behavior (1) and it is the cause of various social problems (2. 3).

There is a demonstrated association between the problems of excessive alcohol use and depression symptoms. Results of a longitudinal study (4) which followed a group of 20.728 from teenagers to young adulthood, indicated that excessive alcohol use and depressive symptoms showed a positive association during the period of adolescence to young adulthood. Elevated levels of depressive symptoms were associated with increased baseline levels of alcohol consumption, especially in women, but with faster growth in alcohol consumption in men.

In a review (5) on the same subject, meaning the relationship between symptoms of major depression and inappropriate consumption of alcohol, Boden stated that the presence of either conditions will double your risk of other problems. The two disorders can not be fully explained by common factors that influence them, but it appears to be causally related disorders. Other evidence suggests that causal association between alcohol and depression is one in which alcohol consumption increases the risk of depression, rather than vice versa. Potential mechanisms underlying causal links include neurophysiological and metabolic changes resulting from exposure to alcohol.

Other authors (6) found that alcohol abuse, depression and suicidal behavior in young people presenting biochemical and genetic correlation. Alcohol consumption is shown to be a distal and proximal cause of the attempted suicide among young people. People with alcoholism and depression that have attempted suicide, often had significantly higher levels of aggression and impulsivity. These factors may have been caused or influenced by the underdeveloped coping skills, and comorbid psychiatric disorders. Such behaviours could be a consequence of childhood abuse, social pressure, low self-esteem and / or delinquency. Some studies suggest that the depression encourage the use of alcohol in the form of self-medication, which then leads to suicide, while others require that the starting alcohol consumption is responsible for increasing the symptoms of depression and suicide thoughts among adolescents.

We proposed a study on some manifestations of self-harm (feelings of sadness, suicidal thoughts and plans) associated with binge drinking among students in Timiş County, România.

MATERIAL AND METHODS

The representative sample of students in the study totaled 2076 students from higher education institutions from Timiş county, 62.49% (1296) girls and 37.51% (778) boys. The average age was 21.09 years with SD 1.48, ages ranging from 18-25 years old.

The method used was the transversal population study based on the use of CORT Questionnaire 2004 on health risk behaviors in adolescents and young people. The questionnaire was validated by the Ethics Committee of the University of Medicine and Pharmacy "Victor Babeş" Timişoara.

The study was conducted with the written approval of the higher education establishments from Timiş. Inclusion of young people in the study carried out only after their expressed consent of each participant in the study, with respect for all the individual rights.

The processing and interpretation of data was done by using modern statistical methods and advanced medical PASW 18 software (SPSS 18) 2010. The value of statistical significance was set at $p < 0.05$, except in cases where the Bonferroni correction was applied, the acceptable threshold level was stated in the text. For ordinal data comparisons we used Mann-Whitney and Kruskal test-Wallis. Chi-square test was used for ordinal data / nominal.

RESULTS

1. Binge drinking. By practicing binge-drinking, or increased consumption of more than 5 servings of alcohol on one occasion, we have found: for boys group 11.6% (89) have practiced binge drinking more than 3 times in the last month, 22.1% (170) have practiced 1-2 times, and 66.3% (510) did not practice binge drinking in the last month; 2.5% for the group of girls (32) have practiced binge drinking more than 3 times in the last month, 8.7% (112) have practiced 1-2 times, and 88.8% (1145) have not practiced binge drinking last month. The frequency of practicing binge drinking is significantly higher in boys than girls, $U = 381\,799$, $z = -12.63$, $p < 0.001$, $r = 0.27$, the size difference is considered small to medium based on the Cohen's criteria (fig. 1).

2. Feelings of sadness. A percentage of 16.6% (127) of boys and 25.1% (323) of girls had experienced feelings of sadness for a longer period of 2 weeks during the last year. Girls had these feelings significantly more often than boys, $U = 450454.5$,

z = -4.49, p <0.001, r = 0.09, the size difference is small.

In the group of boys, 33.6% (32) of those who experienced feelings of sadness practiced binge drinking, and of those who have not experienced these feelings 34.0% (226) have practiced binge drinking. Among boys, we found no significant differences between the frequency of binge drinking and experiencing feelings of sadness or hopeless situations more than two weeks in the past year, p = 0.932 (fig. 2).

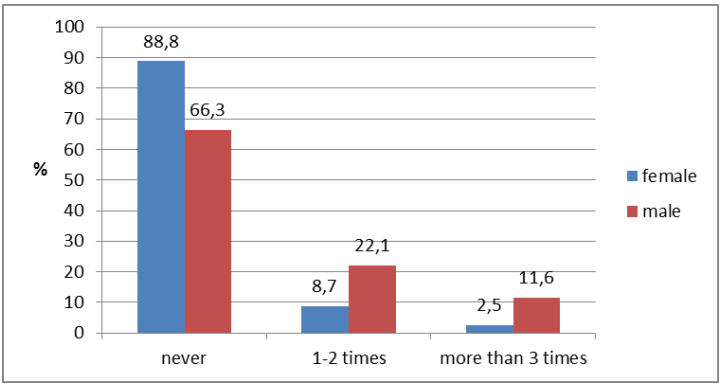

Fig. 1. Percentage distribution of students according to frequency of binge drinking practice last month, by gender

In the group of girls, 17.2% (55) of those who have experienced feelings of sadness practiced binge drinking, and of girls who have not experienced these feelings 9.3% (89) have practiced binge drinking. We found a significantly higher frequency of binge drinking among the girls who have experienced the feeling of sadness, compared to the group that did not experience this feeling U = 141897.5, z = -3.95, p <0.001, r = 0.11, the difference is small in size (fig. 3).

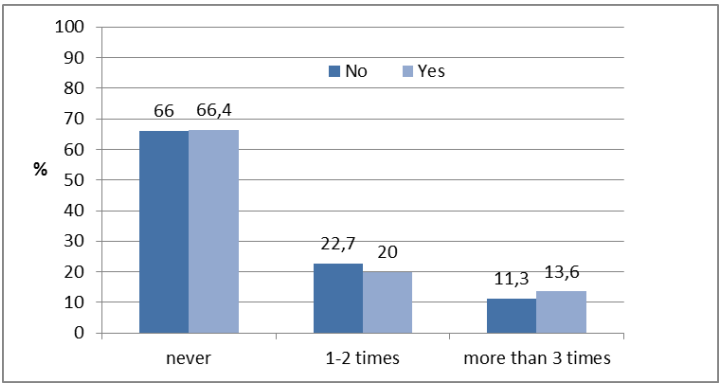

Fig. 2. Percentage distribution of students according to the experience of feelings of sadness or hopeless situations more than two weeks in the past year and frequency of binge drinking practicing during the past month among boys

3. Suicide thoughts. A percentage of 7.2% (55) of the boys and 8.9% (114) of the girls had suicidal thoughts during the last year. Among the girls and the boys we did not find significant differences regarding suicidal thoughts, p = 0.171.

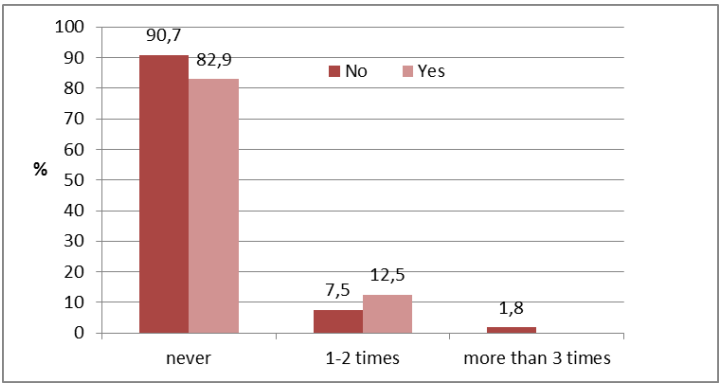

Fig. 3. Distribution of students according to the experience of feelings of sadness or hopeless situations more than two weeks in the past year and frequency of binge drinking practicing during the last month among girls

In the boys group, 34.5% (19) of those who had thoughts of suicide practiced binge drinking, and of those who did not have these thoughts 33.8% (239) have practiced binge drinking. We found no significant differences between the frequency of binge drinking and the existence of suicidal thoughts in the past year, p = 0.873 (fig. 4).

In the group of girls, 19.5% (22) of those who had thoughts of suicide practiced binge drinking, and of those who did not have these thoughts 10.5% (122) have practiced binge drinking. We found a significantly higher frequency of binge drinking in the group who had suicidal thoughts, compared to the group who did not had suicidal thoughts in the past year U = 60 154, z = -2.78, p = 0.005, r = 0.08, the difference is small in size (fig. 5).

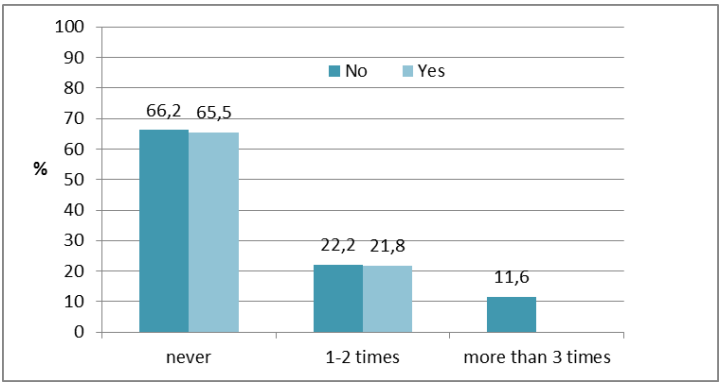

Fig. 4. Percentage distribution of students according to the presence of suicidal thoughts during the past year and frequency of binge drinking practicing in the past month among boys

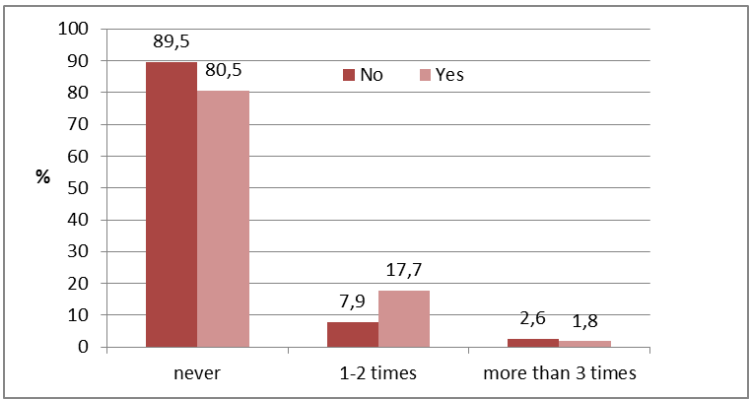

Fig. 5. Percentage distribution of students according to the presence of suicidal thoughts during the past year and frequency of binge drinking practicing in the past month among girls

4. Suicide plan. A percentage of 3.0% (23) of the boys and 2.8% (36) of girls had suicidal plan last year. We did not found significant differences in the presence of suicide plans between girls and boys, p = 0.800.

In the group of boys, 43.4% (10) of those who had suicide plan practiced binge drinking, and of those who did not plan, 33.5% (248) have practiced binge drinking. In boys, we found no significant differences between the frequency of binge drinking and the existence of a suicide plan in the past year, p = 0.343 (fig. 6).

In the group of girls 27.8% (10) of those who had suicide plan practiced binge drinking, and of girls who had no plan, 10.8% (134) have practiced binge drinking. We found a significantly higher frequency of binge drinking in group who had suicidal thoughts, compared with the group who had no suicidal thoughts in the past year U = 60 154, z = -2.78, p = 0.005, r = 0.08, the difference is small difference is small in size (fig. 7).

DISCUSSIONS

Alcohol consumption was associated with depression, but the studies made by Spear (7) failed to determine whether adolescents and young people consume alcohol because of depression or depression occurs due to the toxic effects of alcohol. Research carried out on people who abuse alcohol, found a smaller number of neurons in the *locus coeruleus* from the stem cells of the brain, compared to people who did not use alcohol, suggesting that alcohol could alter brain structure and trigger such a behavior response (8).

Other authors (9) have shown that chronic alcohol consumption in adolescents may increase feelings of depression, due to lower levels of serotonin. The young people involved in the inappropriate consumption of substances, 60% were diagnosed with psychiatric pathologies, according to a study by Armstrong and colleagues (10).

Galaif et al. (11) reported a 100% increase in rates of suicide between 1980 and 1999 in children of 10-14 years and an increase of 14% in those aged between 15-19 years old. They argued that the diagnosis of major depression was the most common reported comorbidity in suicide and alcohol abuse, and there is a mutual synergistic relationship between depression and alcohol abuse. They could not prove a causal relationship between the two diseases.

Groves's study (9) estimates that alcohol would increase the likelihood of suicide 17 times for boys and 3 times in girls. It is possible that adolescents who abuse alcohol have a greater risk of suicidal behavior because each of those two factors, depression and alcohol increase the risk of suicide independently, and together their action is likely to be synergistic.

CONCLUSIONS

In our study, the prevalence of practicing binge drinking 1-2 times in the last month is 22.1% for boys and 8.7% girls and more than 3 times in the last month is 11.6% for boys and 2.5% girls. The boys practice binge drinking significantly more often than girls, the difference size is small to medium.

A percentage of 16.6% of boys and 25.1% of girls had experienced feelings of sadness for a period longer than 2 weeks during the last year. Girls had these feel-

ings significantly more often than boys, the size difference is small. In boys, we found no association between the frequency of binge drinking and experiencing feelings of sadness or hopeless situations more than two weeks in the past year. In girls, the increased frequency of engaging in binge drinking is associated with feelings of sadness, a far small but significant percentage.

A percentage of 7.2% of boys and 8.9% of girls have had suicidal thoughts in the last year, no significant differences between genders. 34.5% boys respectively 19.5% of the girls who practiced binge drinking had thoughts of suicide. In boys, we found no association between the frequency of binge drinking and suicidal thoughts in the past year, but in girls, increased frequency of engaging in binge drinking is associated with suicidal thoughts in a small measure, but significant.

With no differences between sexes, 3.0 percentage of boys and 2.8 of girls have had suicidal plan last year. 43.4% boys respectively 27.8% of the girls who practiced binge drinking had suicidal plan. In boys, we found no association between the frequency of binge drinking and suicide plans in the past year, but in girls, increased frequency of engaging in binge drinking is associated with suicide plans, in a small measure, but significant.

TIME-LAPSE IMAGING AND ITS POTENTIAL TO IMPROVE EMBRYO SELECTION IN IVF (Abstract) Time-lapse imaging has given birth to a new concept in the IVF laboratory, termed morphokinetics. Being a combination of the morphological appearance of the embryo and the events leading to a certain stage of development, morphokinetics offers the embryologist the possibility of correlating certain cleavage parameters with the implantation potential of the embryo. The use of time-lapse imaging offers the possibility of following the embryos in a closed system and detecting the developmental anomalies, making it easy to select the best embryo to be transferred. Studies are being made for a better correlation of the parameters offered by time-lapse imaging with a successful embryo selection. In this literature review we are summarizing the studies that determined and examined the markers of embryo development *in vitro* by time-lapse imaging and the way these markers provide proper information about the chromosomal status of the embryo, its ability to reach the blastocyst stage and the implantation potential. **Keywords**: TIME-LAPSE, MORPHOKINETICS, EMBRYO SELECTION.

In 2010, an estimated 48.5 million (45.0 million, 52.6 million) couples worldwide were infertile. One in every four couples in developing countries had been found to be affected by infertility (1). Infertility has numerous causes, approximately 16% of the individuals with reproductive disorders being affected by chromosomal abnormalities (2). In Romania, as in all modern societies, one cause of population decline is postponement of births (3).

In the last 36 years, since the first successful *in vitro* fertilization (IVF) procedure, significant progress was made in improving the procedure in terms of ovarian stimulation protocols, but also in IVF laboratory technology. Even though success rates have very much improved with time, they are still considered to be low, approximately a 33% clinical pregnancy

rate per transfer (4).

An important role for a high pregnancy rate in IVF procedures is attributed to the selection of the best embryos to be transferred. The selection is usually made using morphological systems that are relying on zygote pronuclear scoring systems, cleavage-stage scoring systems and blastocyst scoring systems. This type of assessment is considered to be subjective because it is associated with intra-observer and inter-observer variability (5). Also, different clinics use different scoring systems, making difficult to compare the results.

In the standard procedure, in order to be able to score the embryos, they have to be taken out of the incubator daily, exposing them to variations in temperature, pH and light which can be detrimental for their future development (6). But because only a few moments of embryo development are observed, a great part of its evolution cannot be seen, so the probability of not observing an abnormal process, for instance the direct cleavage to three cell stage, is high.

The importance of choosing the best embryo for transfer comes also from the fact that multiple pregnancy is considered a complication of IVF procedure. As a result, many clinics have adopted the idea of single embryo transfer. So, obtaining a good pregnancy rate and also avoiding multiple pregnancy needs an improved embryo selection.

Because the present embryo grading systems are applied by the embryologist and are subjective, alternative methods were required for a more objective evaluation that can improve the selection process. Among these, preimplantation genetic screening (PGS) is used for the selection of genetically normal embryos. This is an invasive method that requires the aspiration of the first polar body before the fertilization of the oocyte or of one or two blastomeres from the embryo on the third day after fertilization or by trophectoderm biopsy (7). More recently, blastocyst biopsy and array comparative genome hybridization (array CGH) offer a more complete chromosome analysis and results available within 24 hours (8). Even though these techniques give reliable results, it remains the inconvenience that biopsy could affect the development of the remaining embryo (9) and it is also an expensive technique.

Time-lapse monitoring systems have gained a lot of attention in the past few years. With these systems new biomarkers that could be used in clinical settings for embryo selection are identified. The main advantage of time-lapse markers is their non-invasiveness and the possibility of correlating them with embryo parameters such as their quality, development and implantation potential (10).

This review gives brief consideration to the use of time-lapse biomarkers for human embryo selection, with respect to their correlation with the development of the embryos, implantation potential and the genetic status of the embryos.

TIME-LAPSE SYSTEMS CURRENTLY USED IN THE IVF CLINICS AND SAFETY EVALUATION

Currently there are two main commercially available time-lapse technologies for use in IVF clinics: a miniaturized microscope that can be placed into the incubator and that will capture the entire embryonic development or equipment that includes both the incubator and the image capturing device, each one having specific software

for analyzing the acquired images. Each device has a specific culture plate that can hold 9, 12, 16 or 25 embryos, monitored individually either by moving the slide into the optical field of view or they are cultured in multiwell plates, the embryos being all seen in the same field of view (10). The microscopes used for time-lapse monitoring systems have dark field illumination systems or Hoffman modulation contrast illumination. The problem regarding the safety of time-lapse for the embryos is mentioned because they are repeatedly exposed to light at determined time intervals.

In a study by Wong et al. (10) the embryos were exposed 1 second every 5 minutes for 5 or 6 days. The total light exposure time calculated was approximately 24 minutes, at a power of 0.3 mW, equivalent to a light exposure time of 1 minute (60 seconds) under classical IVF laboratory conditions. Nakahara et al. assessed the fertilization rate, cleavage rate and embryo quality by comparing these parameters for the oocytes of the same patient, fertilized by ICSI, cultured in a conventional incubator and in the same incubator that had an integrated microscope. In the time-lapse systems the embryos were exposed every 15 minutes to 0.1 W LED light. They did not find significant differences between the two groups of embryos (11). When comparing the ongoing pregnancy rate for embryos cultured in a time-lapse monitoring system with that of embryos cultured in a conventional incubator, Rubio et al. (12) found in a prospective randomized, double-blind controlled study that there were significant differences between the two groups (51.4% and 41.7%, respectively).

A randomized clinical trial conducted by Kirkegaard et al. evaluated the safety of time-lapse monitoring by comparing the proportion of 4-cell stage embryos, as a primary endpoint, the proportion of 7-8 cell stage embryos and that of blastocysts, as secondary endpoints, in a time-lapse monitoring system and in a conventional incubator. This study showed no significant differences between the two incubators regarding the proportion of 4-cell embryos, 8-cell embryos and blastocysts. Also there was no significant difference regarding the pregnancy and implantation rate (13).

Although improvements can be done to time-lapse monitoring systems, they appear to be safe for use in IVF laboratory.

CLEAVAGE KINETICS OBSERVED WITH TIME-LAPSE SYSTEMS - BIOMARKERS FOR EMBRYO FATE

Cleavage kinetics observed with the use of time-lapse systems began to gain a lot of attention in the search for non-invasive indicators of embryo implantation potential. Embryos are monitored immediately after the fertilization process and information about the timing of pronuclei appearance and disappearance, cleavage divisions, their synchronicity and the time intervals between these divisions are being measured expecting a correlation with the "normality" of the embryo (14).

There is abundant debate regarding the duration of culture (2, 3, 5 or 6 days) and the optimal day for embryo transfer. The advantage of a shorter culture period, with a day 2 transfer after fertilization, would be the shorter exposure of the embryos to the *in vitro* environment. Prolonged *in vitro* culture could determine epigenetic disorders or obstetrical complications, like preterm delivery (15). Wong et al. (16) laid

the basis of an evaluation system using time-lapse imaging for the best embryo selection, before embryonic genome activation. The time-lapse system captured images every 5 minutes with microscopes with dark-field illumination. The parameters established as being predictive for the potential of the embryo to develop to the blastocyst stage were a duration of 14.3± 6.0 minutes for the first cytokinesis from which two cells result, a duration of the two-cell stage of the embryo, from the first mitosis to the beginning of the second mitosis of 11.1±2.2 hours, a time interval between the second and third mitosis (from three to four-cell stage or synchronicity) of 1.0±1.6 h.

The embryos that have a shorter time interval for the two-cell stage, dividing from two to three cells in less than 5 hours are considered of very poor prognosis for implantation. This time interval is required for DNA replication so if this interval is much shorter there is not enough time for complete genome replication, resulting in embryo aneuploidy (17).

Meseguer et al. (18) also used a time-lapse system to determine specific morphokinetic parameters for embryos with good implantation potential. Image acquisition was done every 15 minutes using optics with modified Hoffman contrast for low intensity red light. The most important parameters for embryo implantation potential seemed to be the time between the 2-cell stage and 3-cell stage (<11.9 hours), synchrony of the embryos, the time from the 3-cell stage to 4-cell stage (<0.76 hours) and the time interval between the injection of the spermatozoa and the formation of a 5 cell embryo (48.8-56.6 hours). The implantation rate for the embryos categorized as A according to the time-lapse parameters was 67%. With the help of time-lapse imaging system it was possible to observe that there are embryos that divide directly to three cells, these embryos having a limited implantation potential. Rubio et al. (19) found that 6.6% of the embryos from their cohort cleaved directly to 3-cell stage with only 1% chance of implantation.

Dal Canto et al. (20) made further research regarding morphokinetic parameters until the blastocyst stage, and correlated the cleavage times from 2 to 8-cell stage with the ability of the embryo to form a blastocyst. The system used for image acquisition was similar to that in the previous study. They found that the time needed for the embryos to get to 7 and 8-cell stage was shorter for those embryos that form blastocyst than for the others (56.5±8.1 h compared to 58.8±10.4 h for 7-cell stage and 61.0±9.4 h compared to 65.2±13.0 h for the 8-cell stage).

The prediction of the ability of the embryos to develop to blastocyst stage was also studied by Cruz et al. (21) as a continuation of the study by Meseguer et al. A hierarchical classification of the morphokinetic parameters was used. They concluded that early embryo cleavage is an indicator for the blastocyst stage potential of the embryo. They also considered synchronicity as an important indicator for the blastocysts with a good morphology.

Desai et al. (22) compiled all the kinetic markers established by previous studies and used them for determining the potential of the embryo to form a blastocyst and to implant. They took into consideration time to syngamy (tPNf), time to 2 cells (t2), 3 cells (t3), 4 cells (t4), 5 cells (t5), 8 cells (t8), morula formation, start of blastulation, time to blastocyst and expanded blastocyst

formation. They also recorded cleavage anomalies and multinucleation. The study showed that the most important parameters were tPNf, time to two, four and eight cells, the synchronous divisions and the duration of the third cell cycle, these being significantly different for the embryos developing to blastocyst stage. The study also showed that 56% of the binucleated embryos and 48% of the embryos with more than three nuclei developed into blastocysts that met the freezing criteria, but still without information regarding the implantation potential.

Even though a final embryo evaluation system using time-lapse based biomarkers hasn't been established yet, there is important progress in this direction that could allow a consensus and application in current practice.

THE CORRELATION BETWEEN TIME-LAPSE BIOMARKERS AND THE GENETIC STATUS OF THE EMBRYO

There are studies showing that early-stage embryos are affected by chromosomal abnormalities which determine a negative evolution of the embryo consisting either in developmental arrest, implantation failure or, if they do manage to implant, various genetic complications of the fetus (23). The incidence of aneuploidy is high regardless of the meiotic (gametes) or mitotic (after fertilization) origin (24). The frequency of chromosomal abnormalities increases with age. A systematic review by van Echten-Aremds et al. (25) regarding the prevalence of chromosomal mosaicism in human preimplantation embryos indicates that 73% of the embryos are mosaic, with two categories: 59% diploid-aneuploid mosaic and 14% aneuploid mosaic. This high rate of mosaic embryos raises the question if PGS really helps improving embryo selection and live birth rate (24). Blastocysts appear to show a smaller proportion of aneuploid cells compared with day 2-3 embryos (25).

Recently, with time-lapse imaging development, the idea of using time-lapse morphokinetic parameters as indicators for the genetic status of the embryos was suggested.

The study of Chavez et al. (26) correlates the cell-cycle parameters of embryos until 4-cell stage and the ploidy status by a-CGH. Their analysis showed that the majority of chromosomal errors have a mitotic origin. The embryos chromosomally normal needed 14.4±4.2 min form the first cleavage furrow to the appearance of two blastomeres, 11.8±0.71 h from two to three cells and 0.96±0.84 h from three to four cells. The aneuploid embryos needed a larger time interval for the appearance of the third cell.

In the classical follow-up, in which embryos are observed only at certain time points, the degree of fragmentation is an important criterion in embryo selection. Chavez et al. indicate that this evaluation has to be done in a dynamic way and has to be correlated with the analysis of cell-cycle events and blastomere asymmetry, using time-lapse imaging. Cellular fragmentation was found in the majority of aneuploid and triploid embryos.

Basile et al. (27) analyzed in a retrospective study the development of embryos cultured for 120 hours in a time-lapse imaging system and correlated this with a-CGH results from day 3 biopsy in order to develop an algorithm for non-invasive selection of chromosomally normal embryos. They found that a large proportion of normal

embryos form 5 cells within 47.2-58.2 hours, the duration of third cell cycle is 11.7-18.2 hours and the interval between the formation of 2 and 5 cells >20.5 hours, the last two parameters being the most relevant for chromosomally normal embryos.

Another study of Campbell et al. (17) followed the embryos until the blastocyst stage, designing an aneuploidy risk model based on the information received from trophectoderm biopsy. These information were compared with the morphokinetic variables determined with time-lapse analysis, classifying the embryos into three aneuploidy risk classes - low, medium and high risk - depending on the time from insemination to the start of blastulation (tSB) and the time from insemination to the formation of a blastocyst (tB) (28). The embryos included in the three classes have a probability of aneuploidy of 0.37, 0.69, and 0.97, respectively. For the low risk class tSB was less than 96.2 hours after insemination and for medium risk class was higher than 96.2. Regarding the necessary time for the formation of a blastocyst, the first two classes needed less than 122.9 hours after insemination for this, while the high risk class required more than 122.9 hours to form a fully blastocyst (17). This study was then applied by the same team in order to analyze the application of this aneuploidy risk model on fetal heart beat rate and live birth rate (28). The results for the embryos included in the low risk class were 72.7% for fetal heart beat and 61.1% for live birth rate indicating that the model offers important information regarding the ploidy state of preimplantation embryos using only morphokinetic parameters observed with a time-lapse system.

Another interesting study of Yang et al. (29) followed implantation and pregnancy rate for sibling embryos cultured in a time-lapse system and in a conventional incubator until the blastocyst stage, all being tested using whole genomic amplification and a-CGH. Even though the first morphokinetic parameters set by Meseguer et al. (18) seemed to be the same for both euploid and aneuploid blastocysts, the pregnancy rate and the implantation rate were significantly higher for the embryos cultured in the time-lapse system because this offers advantages like continuous single culture medium, a better temperature and pH control and a minimal light exposure.

Even though time-lapse imaging systems present numerous advantages, such as the possibility of observing every stage of embryo development, a limited exposure to out of incubator environment and to variations in pH, temperature, light, they also have some limitations. Most studies using time-lapse monitoring of embryos were done on ICSI cycles because these allow the exact determination of fertilization. This cannot be achieved for classical IVF. For these cycles the monitoring can be done after denuding the oocytes the following day, being more difficult to assess time parameters from post-insemination time.

CONCLUSIONS

Time-lapse imaging and the potential correlation between the morphokinetic parameters of embryos and their implantation potential represent an attractive domain for IVF specialists trying to find new methods for selecting the best embryos using noninvasive markers. Currently, in Romania only few fertility clinics use time-lapse systems. There is a need for establishing an algorithm that can be applied in all IVF laboratories with certain parameters referring to embryo development to be used

in embryo selection. At this time we cannot replace PGS with morphokinetic selection of embryos, but substantial progress has been made. A noninvasive alternative to PGS would provide important advantages, with PGS use being prohibitive in terms of availability, costs and legislation. With continuous efforts, time-lapse imaging could be used in the future as a non-invasive alternative to PGS.

Embryo morphokinetics can be correlated with the potential of the embryo to develop to blastocyst stage, the potential to implant, to determine a live birth, considering the cleavage pattern.

Time-lapse imaging provides useful information on in vitro embryo development and progress is still being made in finding biomarkers that can be used in current practice for a better embryo selection.

Our opinion - reviewing current results regarding time-lapse based embryo selection and considering the difficulties that we face in current practice of selection by conventional embryo culture and monitoring pleads for the use of this technique with certain non-inferior results and important potential advantages.

A TODAY VICTIM OF SECOND WORLD WAR (Abstract): Emergency medicine as a medical specialty has to deal with all kind of emergency situations, from medical to post traumatic acute events and from new born to the elderly persons, but also with particular situations like explosions. In Romania nowadays these are accidental explosions and rare like frequency, but may be dramatic due to numbers of victims and multisystem injury that may occur. We present a case of a single victim of accidental detonated bomb, a projectile from the Second World War, which unfortunately still may be found in some areas. The management of the case from first call to 112 until the victim is discharge involves high professional team work. We use these opportunity to make a brief review of the mechanism through the lesions may appear and also to renew the fact that the most impressive lesion may not be the most severe, and we have to examine carefully in order to find the real life threatening injury of the patient. **Keywords:** EMERGENCY, EXPLOSIONS, HEMOPERITONEUM, HEMORRHAGE, AMPUTATION

Although rare, nowadays there are still unexploded projectiles of the Second World War on Romania's territory, mainly found in rural area, near to or in the forests. Even if they look like antiques and appear to be inoffensive, these projectiles may be very harmful in inexperienced hands.

CASE REPORT

At 12:30 of 21.05.2014 there was a 112 call for a teenager of 17 years old who was found bleeding after he manipulated a projectile found on a wild field. The dispatch sent an ambulance and the helicopter and also the fire workers and special intelligences. At 12.40 the emergency team found an conscious but confused victim, Coma Glasgow Scale 14, with opened airway and spontaneous breaths, hemodinamically stable by appearance, BP=150/96 mmHg, HR=100/min, SaO_2=90%, with partial amputation of I-IV fingers of left hand, nasal stopped bleeding and multiple superficial wounds of the thorax and abdomen.

The emergency team provides the first professional aid by fixing a cervical collar, monitoring vital signs, getting two i.v. lines of 18 G and putting a compressive bandage on the fingers of left hand and also a splint for sustaining the forearm. The patient was transported by helicopter sitting on a stretcher, while he was perfused with normal saline and analgesics (Fentanyl 100 mcg i. v.) (fig. 1).

Fig. 1. Multiple superficial wounds on the thorax and abdomen

In The Emergency Department he was continuously monitorized, blood and urine samples were taken and he got an antitetanic vaccine and antibiotics. Left forearm and hand X-rays were done, as well as a contrast computer tomography of the head, neck and toraco-abdominal-pelvic areas which revealed no pathological signs on cranio-cerebral and neck level, but found multiple solid foreign bodies (shrapnels) on thoracic wall without lung or pleural post traumatic sings of injury; there were found pneumoperitoneum and hemoperitoneum mostly in the right hemi abdomen, liver lacerations in segments V-VI, shrapnels in segments II, III, VI, VII and VIII of liver and interhepatogastric, between the intestines and in the abdominal wall and right hemoscrotum. It's worth mentioning than even from body topogram foreign bodies were identified (fig. 2,3).

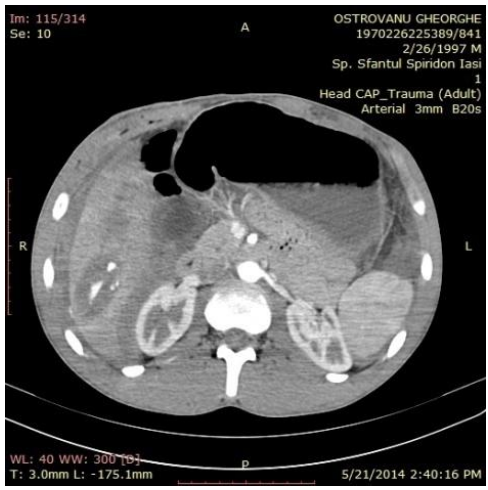

Fig. 2. Liver laceration with active bleeding

Fig. 3. Body topogram showing multiple foreign bodies (shrapnels)

A multidisciplinary medical team (emergency physicians, radiologists, general surgery, orthopedics, ear, nose and throat doctors, oro-facial and plastic surgeons) gathered and decided to do immedi-

ately general surgery intervention to stop the internal bleeding.

Median xifoumbilical laparotomy was performed and when entering in the abdominal cavity hemoperitoneum was found (about two liters of blood). An infracentimetric liver laceration (segment III) and foreign body (shrapnel) with adjacent sub capsular hematoma were identified. The shrapnels were removed, the hematoma drained and afterwards a simple hepatorrhaphy was performed. Further inspection of the abdominal cavity detected multiple transfixiant lesion of the liver (segment V and VI), one of them involving the liver bed with active bleeding unresponsive to haemostatic measures which implied performing tactic cholecystectomy and liver wedge resection (V and VI liver segments). The exploration of the abdominal cavity was continued with dissection of the gastro colic ligament and inspection of retro gastric cavity and mobilization of the superior duodenal flexure, inspection of the bowels and spleen without any source of bleeding. Right persistent patent *processus vaginalis* was found with blood exteriorizing when the hemiscrotum was compressed. A vertical incision was made through the skin of the right scrotum and underlying tissues that found a hematoma that was removed and normal aspect testicle. An orchidopexy was performed and the scrotum was closed. Three abdominal passive drains were placed (right subphrenic space, subhepatic and Douglas) and the abdominal wall was closed in anatomical layers.

Post operatory evolution was good, and the patient remained in intensive care 3 days being monitorized and perfused with normal saline and colloids after he was transfused with plasma during surgery intervention. He also got antibiotics, antiemetic and analgesics.

Although there were no other lesions and the post operatory evolution was good, the teenager remained without first phalanx of fingers I, II, III of the left hand.

DISCUSSION

Even if we live peaceful times, there are rarely cases of accidental blast injuries in Romania and this is the reason why we decided to present a classification of the lesions produced by the explosions and blasts.

In order to understand the mechanism of lesions it is important to know that there are two major types of explosives: high order explosives, which produce a supersonic over-pressurization shock wave (HE) and usually these are the modern military weapons (C-4, Semtex, TNT, nitroglycerin, dynamite, ANFO), and low-order explosives (LE), which develop a subsonic explosion (gun powder, petroleum based bombs, like Molotov cocktails) (1).

Primary mechanism of blast injuries (blast wave) involves intense overpressurization impulse due to detonated HE explosives and affects organs filled with gas (lungs, middle ear, and gastrointestinal tract). The injuries that will be developed are: pulmonary barotraumas, tympanic membrane rupture, eye destructions, brain damage, abdominal hemorrhage and bowel perforation, mesenteric shear injuries, solid organ lacerations, testicular rupture (2, 3).

Secondary mechanism of blasts derive from flying objects hitting the body (parts of the bomb or other adjacent objects) and the subsequent lesions may be eye penetration and blunt or penetration trauma of limbs or body (4).

Tertiary mechanism involves the blast wind which throws away the victims and any part of the body may be affected by blunt or penetrating trauma, fractures and

amputations (5).

Quaternary mechanism is due to all kind of injuries from the explosion like burns, crushes, toxic gases inhaled, asphyxia and complications of chronic pathology (asthma, angina, hypertension, and hyperglycemia) (6).

In our case, was not about HE projectile, so we cannot talk about blast wave, but about blast wind, which caused penetrating and blunt abdominal trauma and secondary mechanism of flying fragments of bomb causing penetrating injuries – shrapnels into the thoracic wall and abdominal wall and cavity and also partial amputation of the left hand fingers.

CONCLUSIONS

Even if explosions are rare circumstances in normal peaceful times, victims of these events usually have multiple traumas and life threatening condition may underlay visible hemorrhage.

NEWS

SAPHENOUS VENOUS GRAFT PSEUDOANEURYSM

Saphenous vein graft (SVG) pseudoaneurysm is a rare and serious complication of coronary artery bypass (CABG) surgery. The complication can vary from an incidental finding on an imaging study to a life-threatening emergency. In the two reported cases, SVG pseudoaneurysm reflects the extreme variation in presentation and natural history, and highlights the need for adapted management. A review of literature indicates that almost one third of patients are asymptomatic at detection and a history of operative complications and need for re-exploration after the initial surgery may serve as useful predictors for the development of this rare complication. Finally, a conservative management may be considered, especially in the asymptomatic patient with multiple co morbidities and limited life expectancy (Smer A, Alla V, Chandraprakasam S, et al. Saphenou Venous Graft Pseudoaneurysm: A Review of the Literature. *J Card Surg* 2015; 30: 70–73).

INTUSSUSCEPTION IN INFANTS – STORM FROM A CLEAR SKY

INTUSSUSCEPTION IN INFANTS – STORM FROM A CLEAR SKY (Abstract): Intussusception is one of the most common causes of acute abdominal conditions requiring surgical therapy in infants and babies. Due to the breakthroughs of pediatric intensive care and imaging methods, which may sometimes replace therapeutic methods, this condition, which used to be associated with high morbidity and mortality rates, is now more easily detected and treated immediately, even by non-surgical means. Nevertheless, there still is a high percent of cases in whom the diagnosis is set relatively late and who require laborious surgical procedures and extensive intestinal resections. These cases have high morbidity rates, the condition sometimes has a negative course and the patients die. We conducted an analytical retrospective study on a group of 49 patients diagnosed with intussusceptions, hospitalized and treated in the Pediatric Surgery Ward of the Children's Hospital of Iași City during 5 years. Although the demographics and clinical presentation of our patients is largely in agreement with literature data, we note that 69.4% of the patients came to the hospital 24 hours after the onset of their symptoms, which delayed diagnosis setting, ruled out non-surgical therapy and thus led to a high rate of postoperative complications (24.5%) and also to a high mortality rate (6.6%). **Key words:** INFANT, INTUSSUSCEPTIONS, SURGERY

Intussusception is one of the most common causes of acute abdominal conditions requiring surgical therapy in infants and babies, with an incidence of 0.66-2.24/1000 children (1). It frequently occurs between the age of 6 and 24 months, and it is considered idiopathic for this age group, being supported by the intestinal peristalsis increase. In other children and adults, the condition usually has a mechanical cause, which is the starting point of intussusception (Meckel's diverticulum, colon polyp, hemangioma and tumor). Most intussusception cases are ileocecocolic, despite the fact that the condition may also have any other location, and they are the result of the ileum and cecum being telescoped inside the colon (fig. 1). Especially when it occurs in an eutrophic infant, who apparently is in a good health condition, with sudden onset consisting of extreme restlessness, reflex vomiting and blood in the stool, spontaneously or on digital rectal exam, the diagnosis is mainly clinical, as imaging methods only confirm it. Due to the breakthroughs of pediatric intensive care and imaging methods, which may sometimes replace therapeutic methods, this condition, which used to be associated with high morbidity and mortality rates, is now more easily

detected and treated immediately, even by non-surgical means. Thus, its early diagnosis and adequate therapy have considerably improved the prognosis of this condition, and the rates of mortality due to intussusception are currently below 2%. Nevertheless, there still is a high percent of cases in whom the diagnosis is set relatively late and who require laborious surgical procedures and extensive intestinal resections. These cases have high morbidity rates, the condition sometimes has a negative course and the patients die (2).

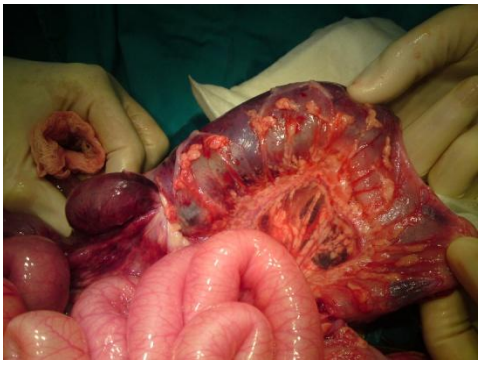

Fig.1. Ileocecocolic intussusception

MATERIAL AND METHODS

We conducted an analytical retrospective study on a group of 49 patients diagnosed with intussusception, hospitalized and treated in the Pediatric Surgery Ward of "Sf. Maria" Children's Hospital of Iaşi City between January 2009 and December 2013. The patients were identified according to the illness code entered into the hospital's computerized data network, the patients' records were identified and retrieved from the clinic's archives, and the following parameters were analyzed: age, sex, clinical signs and symptoms, prior conditions, time elapsed before the patient's coming to hospital, biological and paraclinical tests, conservative or surgical therapy and course of these patients, length of hospitalization.

RESULTS

Two patients whose records were incomplete and two other patients whose intussusception was a postoperative complication of laparotomy performed for other surgical conditions were excluded from the study. 45 patients remained eligible for the study.

Annual incidence ranged from 11 cases in 2009 to 5 cases in 2013, with a mean of 9 cases / year (fig. 2).

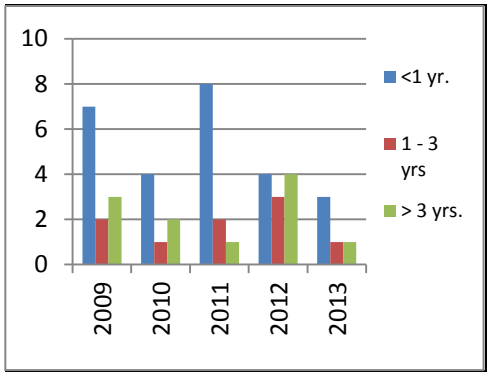

Fig.2. Number of cases per year depending on age.

The average age was 13 months (ranging from 1 month to 17 years), with an incidence peak between the ages of 6 and 8 months. Then the frequency of intussusception decreases with age (tab. I).

TABLE I

Distribution of intussusception cases on age groups

Age	Number of cases	%
0 – 1 year	26	57,7
1 -3 years	9	20
>3 years	10	22,2
TOTAL	**45**	**100**

The gender ratio was 1.5 in favor of boys. Of the 45 children, 19 patients (42.2%) lived in urban areas and 26 patients (57.7%) inhabited rural areas. The time elapsed between the onset of the first symptoms and the patients' hospitalization in our clinic ranged from a few hours to more than 3 days, yet most patients came 24 to 48 hours after symptom onset. The patients were hospitalized in our clinic as follows: 12 cases came directly to us, 17 cases were hospitalized in other clinics (8 cases of acute rhinopharyngitis, 9 cases of gastro-enteritis) and 16 cases were referred to us for suspected surgical conditions (9 cases of intussusception, 3 cases of appendicitis and 4 cases of acute abdominal conditions). The symptoms of the intussusception patients hospitalized in our clinic were dominated by the advent of a state of restlessness due to the child's abdominal pain, vomiting and blood in the stool (spontaneously or on digital rectal exam), and they are shown in table II, which also proves that the classical symptomatic triad occurred in 24 patients (54%).

The physical examination included a digital rectal exam in 50 patients.

Blood was detected in 29 of the cases (66.6%). Intussusception rim palpation during the digital rectal exam combined with abdominal palpations occurred in 5 cases, i.e. 11.1%.

An extremely important element in the study we conducted was related to the time elapsed from the onset of the condition and to the beginning of the treatment, shown in table III, according to which 69.4% of the patients saw a doctor 24 hours after the onset of the symptoms.

Native abdominal X-ray examination was performed in 35 patients and it revealed the results in table IV.

TABLE II

Symptoms of patients with intussusception

SYMPTOMS	Number of cases	%
Abdominal pain	38	85
Vomiting	36	81
Rectorrhagia	32	72.8
Symptomatic triad	24	54
Fever	14	32.2
Diarrhea	2	8
Constipation	3	6.7
Dehydration	2	8
Coughing	1	3.3
Poor general condition	29	66.6
Patient refuses to eat	11	26.6
No transit	3	10
Hematemesis	2	6.6
Abdominal tumor mass	4	13.2
Spasms	1	3.3

TABLE III

Time elapsed from disease onset to the beginning of the treatment

Time	Number of cases	Percent %
< 24 hrs.	13	30,6
24 – 48 hrs.	26	59,4
> 48 hrs.	6	10

TABLE IV

Elements revealed by a simple abdominal X-ray

ABDOMINAL X-RAY	Number of cases	%
Hydro-aeric levels	12	26.6
Dilated loops	10	22.2
Opacity in the right abdominal quadrant	15	33.3
Normal image	17	37.7
Not performed	10	24.4

The intussusception images generated by abdominal ultrasound scanning, which was performed in 40 patients, are illustrated in table V.

TABLE V

Elements revealed by ultrasound scanning in intussusception

ABDOMINAL ULTRASOUND SCAN	Number of cases	%
"Rosette-like" image	26	57.7
Peritoneal collection in Douglas and Morrison space	4	8.8
Abdominal meteorism	10	22.2

A patient whose ultrasound scan and X-ray were not conclusive underwent abdominal CT scanning, which revealed a thickened intestinal wall and the specific "rosette-like" images. As concerns treatment, only three of the 45 patients underwent pneumatic reduction under X-ray control (two were successful and one was a failure). Subsequent surgery was also performed on this latter case.

The surgical procedure consisted of midline laparotomy and manual desinvagination in all 43 cases (95.5%), also followed by bowel resection and termino-terminal anastomosis in 16 cases. Bowel resection was necessary because of the marked ischemia, extended delustered areas due to desinvagination and even intestinal perforation in 12 cases. In four cases (8.8%) bowel resection was aimed at removing the factor that determined the intussusception in the first place, namely two cases of Meckel's diverticulum, one case of intestinal tumor and one case of intestinal polyp (fig. 3).

In all the cases that required bowel resection, the patient saw a doctor 18 hours after the onset of the symptoms. The ileocecal valve was preserved in all the cases. Incidental loose stub appendectomy was also carried out in four patients, due to the alterations in the appearance of their cecal appendix. 34 (75.5%) of the 45 patients had a positive course due to the therapy administered. There were 11 postoperative complications (24.5%), i.e. two anastomosis displacements, two intestinal perforations upstream from the anastomosis, two cases of sepsis originating in the digestive system, one case of kidney failure and one relapse. Three patients (6.6%) died because of generalized peritonitis and severe sepsis, with multiple organ failure (two cases) and generalized metastasis (lymphoma), in one case.

Fig. 3. Meckel's diverticulum (starting point for intussusception)

The average hospitalization time was 3 days for patients undergoing pneumatic reduction, 8.7 days for manual reduction patients and 20.2 days for those who suffered both resection and intestinal anastomosis.

DISCUSSION

The frequency of intussusception detected in our study was 9 cases per year, as compared to 7 up to 49 cases per year reported in other researchers (1, 3). The series-dependent difference in the number of cases is due to variations related to recruitment, expertise and hospital reputation for intussusception diagnosis setting. The highest number of cases was diagnosed in

renowned pediatric surgery centers. In any event, in order to achieve statistical significance, the number of cases reported each year in each specialized service should also be compared with the general population where these cases originate. The intussusception onset age ranged from one month to 10 years in our study, with only few exceptions over this age. Most cases occurred during the first two years of the baby's life, the highest frequency being between the aged of 6 and 9 months. 57.7% of the patients were younger than 1 year, which confirms the predisposition of this age group to intussusception in almost all published series (1, 4). Regardless of the intussusception onset age, the male gender is more affected both in our study and in literature (4). The diagnosis setting time varies depending on the time elapsed from symptom onset to seeking medical attention, and also on the time spent examining the patient until diagnosis setting, which ranged from a few hours to 4 days in our study. Literature reports shorter times in developed countries and similar or even longer times in developing countries (1, 2). This is due to the poor socio-cultural and economic status of disadvantaged inhabitants, who prefer resorting to traditional remedies before seeking medical attention. On the other hand, insufficient training and absence of modern medical examination means lead to misdiagnosing this condition. Thus, all the digestive symptoms are erroneously mistaken for acute gastroenteritis, rhinopharyngitis or other more common pediatric conditions. However, it is true that these pediatric conditions may coexist and may actually constitute a factor promoting intussusception, although most cases occur in eutrophic infants in apparently good health conditions, due to marked peristalsis caused by a more diversified nutrition or by an age-dependent increase in size of Peyer's patches. Other disease-promoting factors are rotavirus vaccinations (5), and other triggering factors in children are colon polyps, hemangiomas, ascaris, Meckel's diverticulum, benign or malignant tumors (6, 7), detected in about 3% of the cases (1), as compared to 8.8% in our study. The symptomatic triad including abdominal pain, vomiting/abdominal tumor burden and rectorrhagia defines the classical for of presentation of intussusception. 54% of the children in our group had all three signs, as compared to 29-33% in literature (1). A recent study argues that the presence of a palpable abdominal mass, crying, vomiting and paleness are the most important clinical signs of intussusception. The association of all these four signs indicates a diagnosis with a 95% probability (8). Digital rectal exam complements the patient's physical examination and it should be done systematically, to support the diagnosis. Digital rectal exam revealed blood in 13 cases (28.8%), and an intussusception rim was felt in 5 cases (11.1%) on digital rectal exam. Imaging examination is merely an additional confirmation of the diagnosis, which is generally a clinical one, relatively simple to set. Abdominal ultrasound scanning or X-rays and sometimes even abdominal CT scanning are absolutely necessary only in older children, in patients that delayed their seeing a doctor or in relapses.

As far as the choice of the most adequate treatment is concerned, it is dependent on age, clinical form; time elapsed from disease onset to diagnosis setting. A conservative therapy is usually preferred. A retrospective study conducted in India reported a 71% rate of surgical therapy and a 0% mortality rate

(4). Unfortunately, only three of the 45 patients underwent pneumatic reduction under X-ray control (two were successful and one was a failure). Subsequent surgery was also performed on this latter case. Unlike literature, which reports success rates that exceed 70% for pneumatic or hydrostatic reduction under ultrasound scanning control (9, 10), the surgical therapy rate was the highest in our study, which suggests that the diagnosis was set late, when the other reduction methods could no longer be used, and the condition was complicated. Early diagnosis is important, since it increases the non-surgical reduction chances and reduces complications risks. Depending on the various series published, the mortality rate has been continuously decreasing lately and is currently below 1% in developed countries (1, 2), as compared to 6.6% in our study.

CONCLUSIONS

Long hospitalization, postoperative complications and their consequences may be prevented by an early intussusception diagnosis setting. Its treatment may be simple and efficient, as it consists of desinvagination by enema or air blowing under ultrasound scanning or X-ray control. Nevertheless, there still is a high percent of cases in whom the diagnosis is set late and who require laborious surgical procedures and extensive intestinal resections. These cases have high morbidity rates, the condition sometimes has a negative course and the patients die.

SURGICAL OPTIONS IN THE TRATAMENT OF PERI-IMPLANT FEMORAL FRACTURES (Abstract) **Aim**: Hip fractures tend to increase as a global number-approx. 300,000/year. Life expectancy of the population is increasing, implicitly the diseases associated with the advanced age are increasing. At the same time, the number of peri-implant fractures (PIF) is increasing. These types of fractures usually have their headquarters at the base of the implant where poor quality bone comes into contact with the rigid implant. Our aim is to identify the factors that influence the production of these types of fractures and to optimize their treatment. **Material and methods:** We analyzed for 6 months, 4 patients with peri-implant fracture of the femur in terms of age, sex, place of origin, type of fracture, treatment type. The surgical treatment applied was different from case to case with favorable postoperative evolution. **Results:** The results from surgical interventions were optimal, assessing fracture stability, restoring mechanical stability, respecting the biological environment, and choosing the right fixation device. **Conclusions:** Peri-implant fractures are a distinct topic in fractures. The long-term implant can alter the bone structure, and may complicate the healing or placement of a new implant, making treatment a challenge for the surgeon. **Keywords:** HIP FRACTURE, PERI-IMPLANT FRACTURE, IMPLANT, SURGICAL TREATMENT.

PIF represent an important problem for the health system due to their increased incidence, the high average age of the affected population and the exorbitant costs that the treatment implies. As the number of implants used in orthopedics increases, it is inevitable that associated fractures become even more common (1, 2).

The trochanteric fractures that generate a large number of PIF account for about half of the total fracture of the upper femoral extremity, although there are also estimates that their number may be 4 times greater than that of the cervical fractures (3). Trochanteric fractures generally occur as a result of high intensity and energy trauma caused by height drops or traffic accidents in young people or hip failure in elderly patients with osteoporosis (4).

The PIF are due to the same forces that cause fracture without the presence of an implant, but on the background of a damaged bone tissue (5) and usually have their headquarters at the base of the implant, where poor quality bone comes into contact with the rigid implant (6).

The treatment of these fractures depends on the age of the patient, the pres-

ence of multiple associated co-morbidities influencing the prognosis, conservative or surgical treatment.

MATERIAL AND METHODS

We analyzed 4 cases of PIF admitted to Orthopedic Clinic of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi between January - June 2017. The data were obtained from the general clinical observation sheets. We analyzed: demographics characteristics of patients: gender, age, origin, type of fracture, interval between first surgery to second fracture (tab. I).

TABLE I

Data analyzed: demographics characteristics, type of fracture, interval between first surgery to second fracture

	Gender	Age (years)	Place of origin	Type of fracture	Second fracture (months)
S.M.	Female	76	Urban	Intertrochanteric fracture	1
E.I.	Female	97	Rural	Trochanteric fracture	84
T.V.	Male	64	Rural	1/3 middle femur fracture	24
C.C.	Female	59	Urban	Intertrochanteric fracture	3

DISCUSSION

Fractures around implants pose unique fixation challenges. The original placement of the implant may predispose to later fracture, the long-term presence of the device may change the structure of the bone and increase susceptibility to fracture, and the implant itself may interfere with healing or the placement of other fixation devices (7, 8).

The techniques for treating PIF may be more difficult, with more limited options and more frequent complications than the techniques used in treating fractures without the presence of an implant.

Treatment of PIF requires strict adherence to the basic principles of treating any fracture. The surgeon must restore the biomechanical integrity of the bone. This requires restoration of a biologic environment in which the bone can heal and a mechanically stable construct to give the bone a chance to heal.

Biology is maintained by strict soft-tissue and indirect reduction techniques, when possible, to preserve periosteal or endosteal blood supply. The surgeon should minimize periosteal stripping, avoid dead space, and consider bone grafting if the biological environment is compromised. The patient's medical condition should be optimized. The patient should be encouraged to stop smoking when applicable.

Mechanical stability is obtained by restoring the anatomic integrity of the bone and by following AO principles with adequate fixation distal and proximal to the fracture (9).

Essentially, all PIF require treatment, and surgical options include the following: a) Revising the implant by placing a new implant, which also stabilizes the fracture; b) Fixing the bone around the implant which include intramedullary devices (rods, nails) and extramedullary devices

(plates, screws)

CONCLUSIONS

Fractures were usually located at the base of the implant, where poor quality bone comes into contact with the rigid implant, due to the difference in resistance between the osteoporotic bone and the implant used for osteosynthesis of the primary fracture.

In our cases PIF represent a challenge because they have presented technical difficulties in fixation and all cases have required surgery. In all cases the stabilization of the fracture focal point was sought, either by implant replacement or by keeping the implant and stabilization.

In geriatric patients with low bone mineral density, we think that diaphysis equal length centromedulary implants offer proper transfer of mechanical stress, preventing peri-implant fractures. Particularly, in proximal hip fractures in geriatric patients we think that long Gamma Nail offer better stability and protection against peri-implant fractures.

OBSTETRICAL TRAUMA - THERAPEUTIC DILEMMAS? (Abstract): Obstetrical trauma is frequent among newborns alive and could represent a cause of perinatal death. The aim of this paper consists of presenting the authors experience regarding the diagnosis and treatment of skeletal and thoracic-abdominal organs related to traumatic birth. **Material and methods**: Between 2000 and 2010, 33 patients with trauma at birth were included in the study. The type of the lesion and the therapeutical approach and results were analyzed. **Results:** Two categories of results were clearly differentiated: excellent for obstetric trauma involving limbs and soft parts and negative, disappointing results with 10 deaths in 12 cases treated for obstetric trauma of abdominal organs. **Conclusions**: Bone and soft tissue birth trauma are relatively easy to identify and treat, but the medical approach of thoraco-abdomnial organs birth trauma need clinical experience and technical possibilities. **Keywords:** OBSTETRICAL TRAUMA, DIAGNOSE, PERINATAL.

Obstetrical trauma occurs with a frequency of 6-8% among newborns alive and totals approximately 2% of all causes of death in the perinatal period (1).

Risk factors for obstetric trauma are known, and depend on the mechanism of birth, fetal organomegaly, the existence of a tumor or malformation, the maternal constitution (2). There have been important advances in the detection of obstetric trauma predisposing situations especially by obstetrical ultrasound (3, 4). The method allowed the identification of risk factors for obstetrical trauma and caused the modification of pregnancy monitoring and childbirth decision. Improved birth assistance techniques, increased frequency of "Caesarean" interventions applicable to the cases with difficult expulsion decreased the number of cases that required the use of forceps.

Unfortunately, there is "spontaneous" birth trauma, in case of mechanical uncomplicated births influencing the natural passage of the fetus or births by "Caesarean" section (5).

The aim of this paper consists of presenting the collective experience of Pediatric Surgery and Orthopedics Department, "Sf. Maria" Emergency Children Hospital of Iasi regarding the diagnosis and treatment of a category of injuries - skeletal and thoracic abdominal organs - related to traumatic birth.

We started from the premise that the diagnosis and treatment of obstetrical lesions is encoded and accessible to the authors. In the cases presented were recorded different types of situations where the application of classical precepts of diagnosis and treat-

ment were not enough, those situations generating discussion on therapeutic strategy but also ethical controversy.

MATERIAL AND METHODS

Between 2000 and 2010, were admitted to the Pediatric Surgery Clinic Iasi 182 newborns of which, 33 patients were included in the study. The inclusion criteria were trauma at birth resulted in bone fractures or various obstetrical injuries suspected in the clinical context of laborious birth (skin lesions, chest or abdominal trauma).

The 33 cases had obstetrical trauma:

- Skeletal: clavicle fracture 2 cases, femur fracture 5 cases, and humerus fracture 2 cases.

- Obstetrical brachial plexus palsy 6 cases

- The soft tissue: skin dilacerations 2 cases, hematoma and ecchymosed 4 cases.

- Internal organs: chest-spontaneous pneumothorax in 6 cases, esophageal perforation in one case and abdominal: liver rupture 3 cases and ruptured spleen 2 cases.

Treatment differed according to the character of the lesions. For bone and peripheral nerve lesions, conservative treatment was performed with different ways to immobilize the affected segments according to classical schemes, specific to each type of lesion. For cases with peripheral nerve injury medical rehabilitation was utilized and soft tissue lesions were treated with simple wound care treatment.

The 12 cases of thoracic or abdominal trauma had the following treatment:

- six cases had chest drainage: 5 for pneumothorax and one for esophageal perforation.

- one case of pneumothorax received ventilatory assistance.

- four cases of hemoperitoneum: 2 cases with liver dilacerations and 2 cases of splenic rupture have undergone surgery: laparotomy, hemostasis in cases with liver dilacerations and splenectomy in patients with splenic rupture.

- one case of hemoperitoneum by liver dilacerations received fluids compensation treatment, transfusions and haemostatic treatment.

RESULTS

There were two clearly differentiated categories of results: excellent cure for obstetric trauma cases - limbs and soft parts and negative disappointing results with 10 deaths in 12 cases treated for obstetric trauma of abdominal organs.

Two patients with thoracic injuries resulted in pneumothorax (one patient with esophageal perforation and one patient treated with ventilatory assistance) evolved favorably.

DISCUSSION

Fetal trauma during birth must be clearly distinguished from fetal trauma produced during pregnancy. Far from being a rarity, diagnosis and treatment of fetal trauma involves saving two lives-the mother and fetus (6). It is recognized that the extent of injury suffered by the mother does not correlate with the degree of fetus damage (7).

The diagnosis of obstetrical trauma is considered simple and does not require sophisticated explorations. In addition, prenatal ultrasound that can detect risk factors for obstetrical trauma occurrence proved extremely useful.

Our experience, revealed by the cases presented here, clearly distinguished two categories of obstetrical trauma: the skele-

tal and soft tissue lesions and the internal organs (spleen, liver). The first group received standard treatment: immobilization, recovery, local care and have very good results with patients healing. The second group received conservative - resuscitation, transfusions - or surgical treatment - laparotomy, surgical hemostasis (8, 9). Disappointing results, 10 deaths recorded in 12 patients with parenchymal organ damage raised the question of choosing the best treatment strategy beneficial to the patient. We believe that clinical experience is to decide when laparotomy is performed in a newborn with haemoperitoneum. Although there is a trend to lower incidence of obstetrical trauma, unexpected maneuvers applied in the attempt of fetus resuscitation by chest compression can cause liver or splenic rupture and hemoperitoneum. Subcapsular ruptured trauma is less severe than liver dilacerations.

Treatment strategy in cases of abdominal parenchymal lesions referred to prompt volume replacement, correction of coagulation deficits and even surgery by laparotomy, blood evacuation from the peritoneal cavity and liver dilaceration suture. Neonatal liver suture is extremely difficult and only the products for haemostasis improvement -TachoComb, Tachosyl - proved effective. We thought that if the patient is hemodynamically balanced, simple clinical surveillance, hematologic and ultrasound is the most practical approach (8).

Another category of obstetrical trauma was the immediately after birth installed pneumothorax, due to a spontaneous esophageal perforation (10) or hyperventilation due to high pressure in infants who required resuscitation. In these cases air leakage collection was evacuated or mechanical ventilation with positive end-expiratory pressure and minimizing the inspiratory pressure peak applied (11).

Skeletal lesions registered at birth as a result of obstetrical trauma generally have good prognosis and complete healing of the lesions was observed (6). Knowing these facts, would prevent dissemination in the media of subjects without medical support! In addition, pediatric neonatologist together with the surgeon are required to distinguish between obstetrical fracture happened in extracting the fetus and postnatal fracture. Practical experience of the authors says that this is difficult and only in case of a fracture injury diagnosis the so publicized "malpractice" could come in discussion.

CONCLUSIONS

The authors report two distinct categories of obstetric trauma: the skeletal and soft tissue and the abdominal and chest.

Bone and soft tissue lesions are more common, easily diagnosed and treated only conservatively, healing without sequelae.

Parenchymal organ injuries are serious, with a high mortality rate. Treatment strategies are multiple and only clinical experience can determine the best choice.

Medical practice must differentiate lesions produced during birth of those produced during fetal life or postnatal.

COMPARATIVE EVALUATION OF SERUM C-REACTIVE PROTEIN LEVELS IN CHRONIC AND AGGRESSIVE PERIODONTITIS PATIENTS AND ASSOCIATION WITH PERIODONTAL DISEASE SEVERITY

C-reactive protein (CRP) is an acute-phase reactant and has been proved to be a significant predictor of future cardiovascular events. Recent studies have demonstrated a correlation between periodontitis and elevated C-reactive protein levels. Most of the studies have focused on chronic periodontitis and very few studies are done in patients with aggressive periodontitis. The aim of a study realized by a group of indian researchers was to determine and to compare the relative levels of serum CRP in aggressive and chronic periodontitis patients. A total of 75 systemically healthy subjects were divided into three groups: group I (non-periodontitis subjects); group II (chronic generalized periodontitis patients) and group III (generalized aggressive periodontitis patients). All participants were subjected to quantitative C-reactive protein analysis using enzyme-linked immunosorbent assay. Mean CRP levels were significantly greater in both group II and III as compared to group I and group III having greater level than group II. CRP levels positively correlated with the amount of periodontal destruction as measured by probing depth and clinical attachment loss. The study indicates a positive correlation between C-reactive protein and periodontal disease severity with particular concern in younger individuals that could be a possible underlying pathway in the association between periodontal disease and the observed higher risk for cardiovascular disease in periodontitis patients (Goyal L, Bey A, Gupta ND, Sharma VK. Comparative evaluation of serum C-reactive protein levels in chronic and aggressive periodontitis patients and association with periodontal disease severity. *Contemp Clin Dent*, 2014 ; 5 (4) : 484-488).

SERTRALINE INFLUENCE ON MORPHINE-INDUCED CONDITIONED PLACE PREFERENCE IN RATS

Diana Ciubotariu, M. Nechifor
University of Medicine and Pharmacy "Grigore T. Popa" - Iaşi
Faculty of Dental Medicine
Discipline of Pharmacology

SERTRALINE INFLUENCE ON MORPHINE-INDUCED CONDITIONED PLACE PREFERENCE IN RATS (Abstract): Serotonine reuptake inhibitors are an important pharmacological arsenal for treating major depression, a severe disease with poorly understood pathogenic mechanisms. Also, little is known about the action of antidepressants on reward system, the function of which is severely affected in this disorder. **Aim:** To assess the influence of sertraline on brain reward system by conditioned place preference technique in rats. **Results**: Both 3 and 5 mg/kg doses of sertraline determined a significant rewarding effect, whereas only the 5 mg/kg dose increased the morphine-induced rewarding effect (in the morphine-only group time spent in the conditioning chamber increased by 184.92±21.43% post-conditioning vs. pre-conditioning, whereas the increase was 195.56±18.3% in the group treated with morphine and sertraline 5mg/kg, $p<0.05$). **Conclusions**: The stimulant effect of sertraline on brain reward function might be involved in its therapeutic efficacy. **Keywords**: REWARDS SYSTEM, MORPHINE, SERTRALINE, CONDITIONED PLACE PREFERENCE.

Major depression (MD) is a disease which produces lots of disturbances in brain functioning. MD mechanisms are still insufficiently known. Antidepressant medication is one of the most frequently used in psychiatric practice. This medication has multiple action mechanisms. Most patients diagnosed with major-depression are nowadays treated with tricyclic antidepressants or with serotonin and/or norepinephrine reuptake inhibitors. Sertraline is one of the most often used serotonin-reuptake inhibitors in patients with major depression and bipolar disorder (1, 2, 3). There are also other important therapeutic uses for sertraline, including social phobia (4), panic disorder (5), or posttraumatic depression.

Brain reward system is essential for human and animal behaviour. Disturbances in its regulation are involved in the pathogenic mechanisms of several psychiatric diseases. One of the most important problems is the way in which different classes of antidepressant medication influence the brain reward system. The data on sertraline actions on reward system or any of is structural components are very scarce (in both humans and animals) (6). The aim of the present study was to investigate the effects of sertraline on reward system and its influence on morphine-induced conditioned place preference in rats.

Conditioned place preference (CPP) is an experimental protocol used to evaluate reward (drug or natural reward) in laboratory animals. The methods explores the associations between the rewarding effect of the addictive substance and other stimuli

(usually from the external environment) arbitrarily chosen.

MATERIAL AND METHODS

The present experiments were performed on adult male Wistar rats (180-270 g) hosted in individual cages; water and food were provided *ad libitum*, except for the behaviour testing periods. Animals were exposed to a 12/12- hour light-dark cycle; testing was performed during the light period. The conditioning apparatus (Panlab, Barcelona) consists of three chambers: two main chambers, distinguished by different wall and floor patterns, situated to the edges of the apparatus (one with black the other with white walls), and one smaller intermediary chamber. Communication between chambers may be either open or closed (by inter-changeable guillotine-like separations, suitable for a 180º movement). Illumination conditions were standardized by placing bulbs above each chamber. Prior to pre-conditioning, animals are subject to habituation sessions (2 sessions of 30 minutes daily, 2 days and one day before pre-conditioning). To induce morphine CPP we used the method described by Tzschentke (7).

1. *Pre-conditioning* (day 1) - natural animal preference towards one of the main chambers was determined. The rat spent 15 minutes in the apparatus (open communication between chambers). Time spent in each chamber was measured; the main chamber where it spent more time was referred to as *preferred* chamber, and the other as *non-preferred*. 2. *Conditioning* (days 2 – 9). Communication between chambers was closed. Days 2, 4, 6 and 8: the rat was restricted for 40 minutes to the preferred chamber, immediately after morphine (3 mg/kg, subcutaneously) administration. Days 3, 5, 7 and 9: alternatively, the rat was restricted for 40 minutes to the non-preferred chamber, immediately after the administration of 1 mL/kg saline solution. 3. *Post-conditioning* (day 10) - preference to main chambers was again measured for 15 minutes (open communication between chambers). Pre-conditioning, conditioning and post-conditioning stages took place in standard illumination conditions, during the same period of the day, in the absence of other stimuli that might have an influence on behavior (8). Pre-conditioning was initially applied to 80 rats. Animals showing a high preference towards a certain chamber (those spending more than 60% of the pre-conditioning time in any of the main chambers, or more time in the intermediary chamber than in any of the main ones) were excluded from further testing. Thus, 12 such animals (15% of the initial test group) were excluded. Of the remaining 68 animals, by applying homogeneity criteria 60 rats divided into 6 groups of 10 rats were selected for further tests.

According to the treatment received on experiment days 2, 4, 6 and 8 during the conditioning phase, the groups received: SS: saline solution (NaCl 0.9%), 1 mL/kg; Morph: morphine, 3 mg/kg; Sertr 3: sertraline, 3 mg/kg; Sertr 5: sertraline, 5 mg/kg; Morph + Sertr 3: morphine, 3 mg/kg + sertraline, 3 mg/kg; Morph + Sertr 5: morphine, 3 mg/kg, + sertraline 5 mg/kg; injected solutions were prepared so that each animal received 1 mL solution/kg at every administration. Doses were adjusted to animal weight changes during the experiment. On days 2, 4, 6 and 8 of the experiment, the rats received the previously described treatment, and then were placed in the non-preferred chamber. Morphine was administered subcutaneously, immediately before placing the animal in the non-preferred chamber; *sertraline* was administered intraperitoneally 2 hours before mor-

phine. On experiment days 3, 5, 7 and 9 all animals received saline solution, 1 mL/kg, and were placed immediately in the preferred chamber. Saline solution was administered intraperitoneally. Interpretation: a significant increase in time spent in the non-preferred (conditioning) chamber (preconditioning vs. post-conditioning) indicates that CPP was induced (change in preference). In such a case, it is believed that this is due to the fact that the animal associates reward (pleasant, euphoric effect of morphine administration) with the morphine-associated chamber.

The obtained results were statistically interpreted (p-value, t-test: paired – to compare post-conditioning vs. pre-conditioning time in each group; independent – to compare variance between groups in which CPP had been induced).

RESULTS

As expected, morphine determined a significant increase of time spent in the conditioning chamber (form 218.9±24.73 seconds – preconditioning, to 466.3±73.46 seconds, post-conditioning, $p<0.001$), indicating that a conditioned place preference was obtained. However, a significant conditioning effect was obtained with both sertraline doses (3 and 5 mg/kg), the effect of the 5 mg/kg sertraline dose being significantly higher compared to the 3 mg/kg dose (tab. I).

TABLE I

Time spent in the conditioning chamber (pre-conditioning vs. post-conditioning)

		Time spent in the conditioning chamber (pre-conditioning) (seconds)	Time spent in the conditioning chamber (post-conditioning) (seconds)	Statistical significance (preconditioning vs. post-conditioning)
Morphine	Average	218.9	466.3	$p<0.001$
	Standard deviation	*24.73*	*73.43*	
Sertraline 3mg/kg	Average	217,5	254.8	$p<0.05$
	Standard deviation	*23.42*	*41.01*	
Sertraline 5mg/kg	Average	238.7	286.9	$p<0.01$
	Standard deviation	*40.01*	*36.11*	

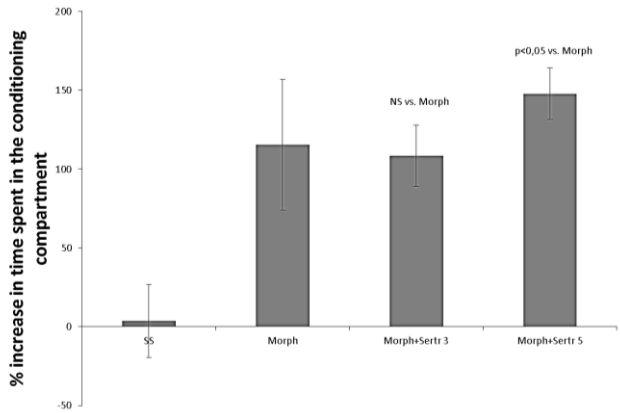

Fig. 1. Variation of time spent in the conditioning chamber (% post-conditioning *vs.* pre-conditioning)

The conditioning effect of sertraline slightly, but significantly potentates the conditioning effect of morphine, but only if higher sertraline doses are used (fig. 1).

DISCUSSION

Addictive substances, as well as natural rewards (water, food, copulatory opportunity) may induce CPP. Bardo and Bevins, (9) enumerated the substances able to induce CPP. Morphine is one of the main addictive substances with rewarding effects proven by this paradigm. Brain reward system represents a system with important involvement in human and animal behavior. This system normal function is also impaired in major depression.

There are very few data regarding sertraline effects on brain reward system in both humans and animals, as well as its effects on different structures belonging to this system. Sertraline is an antidepressant, serotonin reuptake inhibitor, used in the treatment of major depression. This drug has the advantage of relatively few heart side effects (1, 2). Sertraline reduces anxiety and panic, having long-term effect. On the other hand, it has been shown that selective serotonin reuptake inhibitors (SSRI) have important anxiogenic effect. For example, fluoxetine (2.5-10 mg/kg, i.p.) and sertraline (15 mg/kg, i.p.) induce anxiety-like effects (decrease in time of total social interaction and increase in self-grooming compared to vehicle) under low-light, familiar arena test conditions. All these effects were reversed by pretreatment with the highly selective 5-HT2C receptor antagonist. SSRIs also produce anxiogenic effects in animals tested by the elevated plus-maze test (10, 11). We believe that sertraline effect on reward system is also due to receptor-mediated action. Our results are in agreement with other authors, showing that sertraline (2.5-10 mg/kg) induces CPP (12).

CONCLUSIONS

Sertraline, both 3 and 5mg/kg, induced a significant place conditioning. Also, sertraline 5 mg/kg significantly potentiated the rewarding effect of morphine, evaluated by conditioned place preference. We believe that the action of sertraline of stimulating brain reward function might be, at least partially, involved in its antidepressant action and explains its therapeutic efficacy.

LAWSONIA INERMIS-MEDIATED SYNTHESIS OF SILVER NANOPARTICLES

Lawsonia inermis mediated synthesis of silver nanoparticles (Ag-NPs) has been studied by a group of researchers led by Gupta, in order to demonstrate its efficacy against *Candida albicans*, *Microsporum canis*, *Propioniabacterium acne* and *Trichophyton mentagrophytes*. In this study, a two-step mechanism for bioreduction has been proposed, as well as the formation of an intermediate complex leading to the synthesis of nanoparticles and an antimicrobial gel for *M. canis* and *T. mentagrophytes*. The synthesis of Ag-NPs was done using the leaft extract of *L. inermis* in the presence of 1 mM AgNO3 and the compounds were further characterized by Ultraviolet-Visible spectrophotometer and Fourier transform infrared spectroscopy. The size of Ag-NPs was determined by transmission electron microscopy, nanoparticle tracking and analysis sytem. The antimicrobial activity was determined using disc diffusion method. The study concluded that Ag-NPs, due to their biogenic nature, may represent a better candidate drug and an answer to the drug-resistant microorganisms. (Gupta A, Bonde SR, Gaikwad S st al. PARAGANGLIOMA OF THE CAROTID BODY: CASE REPORT (Abstract): With an incidence of 0.03% of all tumors, carotid body tumors (CBTs) are extremely rare. We present the case of a 63 year old female patient with an asymptomatic right sided neck mass of 3 cm diameter. Doppler ultrasound and contrast-enhanced CT confirmed the clinical suspicion of carotid body tumor. The patient underwent complete surgical excision of the Shamblin group II tumor and an adjacent lymph node, without preoperative embolization. The histopathological examination diagnosed a benign CBT. There were no postoperative complications at 1 and 6 months follow-ups. **Keywords**: PARAGANGLIOMA, CAROTID BODY TUMOR, SURGICAL TREATMENT.

Carotid body tumors (CBTs), also known as paragangliomas (PGLs) or glomus tumors, are very rare, with only a few vascular surgeons having encountered such pathology during their career. However, they are the most common para-gangliomas of the head and neck (1) The very few studies on PGLs cited by the literature report contradicting male to female ratios (2-5), but agree the tumors are predominantly unilateral, with more than 50% on the right side of the neck. The mean age of presentation is between 49-55 years and recurrence rate is low (2, 3, 4).

The usual clinical presentation is an asymptomatic, slow-growing neck lump with Fontaine's sign (horizontally mobile, vertically fixed) (1, 2, 4, 5). In few cases, the CBT can cause various pressure symptoms: pain, cranial nerve palsy, dysphagia, odynophagia, hoarseness, dysphonia (1-4) or carotid sinus syndrome like symptoms: palpitations, fainting, falling (4, 5, 6).

Different imaging modalities are used preoperatively, most patients having multiple investigations. Doppler ultrasound (DUS) offers a non-invasive modality of diagnosing CBTs, which appear as solid, well-defined, hypervascular masses causing splaying of the carotid arteries. One series of patients reported CTA as the primary imaging modality, although most of those patients have been followed with DUS as well4. MRI is also effective for diagnosis, as is PET scan for tumors that are less than one cm in diameter (1). Historically, angiography has been advocated as mandatory for preoperative management of CBTs, as it

was shown to reduce the tumor mass and blood flow making surgical resection easier (3, 7, 8). More recent studies did not confirm the difference in blood loss and morbidity between embolized and non-embolized groups (9, 10).

CBTs can be classified as sporadic, familial or hyperplastic, with the former being the most frequent type. The familial type is encountered in only 20% of the cases and follows an autosomal dominant pattern of transmission (1, 19). Malignancy has been reported in less than 5-6% of all tumors (4, 11). It is generally accepted that malignancy is defined only by confirmation of metastasis in non-neuroectodermal tissue (12).

The recommended treatment of CBTs is complete surgical resection, with or without vessel reconstruction (1). Adjunctive therapy such as radiotherapy is reserved for metastatic disease, including patients with locally advanced extension that makes curative resection impossible. To aid preoperative surgical planning, Shamblin introduced a classification scheme that divides CBTs in three groups according to size and local extension. First group consists of tumors that are small and easily removed. Group II includes tumors adherent to or partially surrounding vessels. Group III consists of tumors surrounding or encasing the vessels (13).

The classical surgical technique starts by ligation of the external carotid artery feeding branches, followed by dissection of the tumor from the carotid bifurcation towards the cranial side, in a sub adventitial plane. However, it has been shown that blood loss and cranial nerve injury can be improved with a modified technique that describes dissecting the tumor in a craniocaudal direction, following the course of the ascending pharyngeal artery, suggested to be the tumor's main blood supply (14).

Although the most frequent postoperative complication after CBT resection is cranial nerve palsy that resolves with time (15), a number of other complications have been described: uncontrollable hypertension16, unilateral blindness (17) and persistent Horner's syndrome (18). Mortality rates are between 0 and 3% and stroke rates between 0 and 8% (1).

Routine follow-up consists of clinical evaluation after 4-6 weeks and duplex ultrasound each year. CT or MRI is performed if new pathological findings occur on ultrasound (3).

CASE REPORT

A 63 years old female patient was admitted in our Vascular Surgery Department in May 2013 complaining of a 3 cm asymptomatic right sided neck mass. Her previous medical history included right sided breast cancer 35 years before, surgically treated with right mastectomy combined with axillaries clearance, and non-Hodgkin's spleen lymphoma 6 years before, surgically treated with splenectomy followed by chemotherapy. At the time of admission, she was also being treated for high-risk grade III hypertension. As the patient was diagnosed with a sporadic CBT, no family screening was necessary.

Doppler ultrasound of the mass revealed a highly-vascularized tumor splaying the internal and external right carotid artery and also partially compressing the right internal jugular vein. A lymph node cranial to the tumor was also identified.

Contrast-enhanced CT of the neck and thorax revealed a 3 cm diameter mass located in the right carotid area, partially calcified in the lower segment, with intense

annular contrast intake and post contrast hypo dense center, without evidence of extension to adjacent structures. The tumor had the same size compared to the preview CT scan performed 10 months earlier (fig. 1, 2).

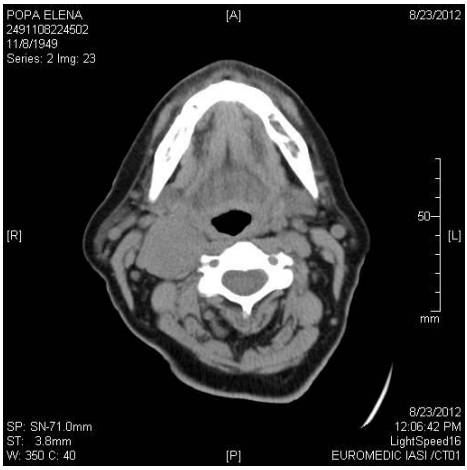

Fig. 1. Native CT

Fig. 2. Contrast CT

Complete surgical removal of the tumor was performed under general anesthesia. The standard incision for carotid endarterectomy on the inner edge of the sternocleidomastoid muscle was undertaken. The common and internal carotid arteries were isolated with vessel loops, while the external carotid artery was clamped. Sub adventitial dissection of the tumor was then carried out from the carotid bifurcation in a cranial direction.

Excision of an adjacent lymph node completed the surgical procedure. The tumor was classified as belonging to Shamblin's group II (fig. 3, 4).

Histopathological examination of the excised tumor and lymph node, characterized the mass as a benign CBT. The lymph node had normal architecture and sinus histiocytosis (fig. 5, 6).

Encapsulated nodular formations with insular or trabecular architecture consisting of polygonal cells with vesicular monomorphic nuclei, having nucleoli with fine chromatin and pale eosinophilic vacuolar cytoplasm. Stoma highly vascularized, with areas of edema and hemorrhage. (HE staining, 10X magnification)

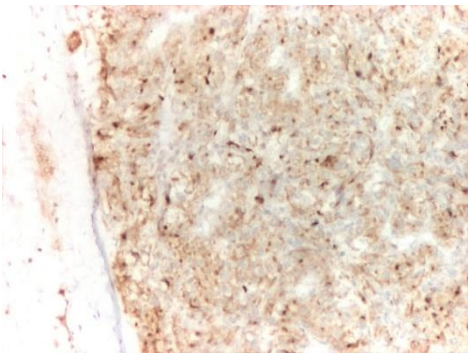

Fig. 6. Chromogranin- positive tumor cells (IHC, Ac anti-chromogranin, magnification 10X)

There were no immediate postoperative complications. The patient remained asymptomatic and complication free at clinical and Doppler ultrasound follow-up after one and six months postoperatively.

DISCUSSION

In patients presenting with swelling of the lateral neck, cranial nerve palsies, voice changes or auditory defects, a PGL of the neck should be included in the differential diagnosis. Careful evaluation of family history of tumors is important. Diagnosis is made on both clinical and imaging criteria. Our patient presented with a 3 cm asymptomatic right sided neck mass, highly suggestive for a carotid paraganglioma.

Imaging procedures, which include a mandatory ultrasound of soft tissue and vessels of the neck and CT or magnetic resonance angiogram (MRA) are recommended preoperatively. On ultrasound the tumor appears as a homogeneously hypoechogenic mass, while on Doppler scan a multidirectional hypervascularization is the main feature. Due to contrast medium enhancement the tumors give high signal intensity on MRA. The Shamblin groups can be predicted preoperatively on MRI.

CT can be useful to reveal relevant bony erosions or punctuate calcification in the tumor (20). To reduce radiation exposure and improve soft-tissue visualization, MRA is preferred to CT (20). DUS confirmed the clinical suspicion of a CBT for our patient and contrast-enhanced CT helped plan the surgical resection.

The clinical value of embolization is discussed controversially in the literature (10, 18, 21, 22). It can be considered in large tumors, because hypervascularization can be challenging during surgery. The risk for neurologic complications such as transient ischemic attacks (TIAs) or stroke caused by angiography or embolization is considerable. In large tumors surgical resection can be facilitated by preoperative embolization. Our patient had a Shamblin

group II CBT, and therefore we decided the risks of embolization outweighed the benefits.

Complete surgical excision is the aim of any operative procedure for PGL and is the only curative option (22). Tumor doubling time is very slow and lies between 4 and 14 years; hence conservative treatment, such as a wait-and-see strategy, can also be discussed in elderly patients, who are free of PGL symptoms but do have other comorbidities. Ipsilateral lymphadenectomy should be performed simultaneously to identify malignant tumors. In these tumors malignancy is defined by metastases in non-neuroendocrine tissue (21). Complete resection of the tumor and excision of an adjacent lymph node was carried out in the case presented.

To reduce intra-operative bleeding, temporary clamping or ligation of the external carotid artery (ECA) may be required. Clamping but not ligation of the ECA was necessary during our surgical resection procedure, to minimize blood loss and improve cranial nerve detection. The larger the tumor the bigger the risk for inevitable nerve lesions or additional vascular procedures increases during surgery (4). Treatment in specialized vascular surgery centers is advisable because the incidence of vascular reconstructions is more than 25%.

Good blood pressure control is recommended. Baroreceptor failure syndrome (BFS) was described by Toma and Netterville and found in 16% of cases (23, 24). It might occur in patients after bilateral resection of the carotid glomus with postoperative acute hypertension and tachycardia. No complications were noted at 1 and 6 months postoperative follow-ups for our CBT patient.

Urinary vanillylmandelic acid and urinary or plasma metanephrine preoperative determination is important if an extra-adrenal tumor is suspected. Early diagnosis and surgical treatment of tumors before the tumor reaches 3 cm is recommended in order to avoid intra-operative nerve damage.

The patient must be referred to a surgeon who is familiar with the head and neck region and has the technical options for vascular reconstruction.

After histopathological confirmation of the paraganglioma, genetic testing and family examination is recommended.

CLINICAL, EPIDEMIOLOGICAL AND PROPHYLACTIC ASPECTS OF DYSPEPSIA

Cristina Brujbu[1] Andreea Macovei[2]
University of Medicine and Pharmacy "Grigore T. Popa"- Iaşi
Faculty of Medicine
1. Discipline of Family Medicine
2. Discipline of Rheumatology-Balneophysiotherapy

CLINICAL, EPIDEMIOLOGICAL AND PROPHYLACTIC ASPECTS OF DYSPEPSIA (Abstract): Dyspepsia or indigestion is a term that refers to a multitude of symptoms and disorders of the digestive system which cause suffering in many patients. Dyspepsia means pain or discomfort that is centrally localized in the upper abdomen. The following categories of symptoms may also be present: pain localized in the right or left hypochondrium, dysphagia, upper gastrointestinal bleeding, acute abdomen, symptoms of reflux, transit disorders. On the other hand, the term "discomfort" was defined in order to designate a condition characterized by or associated with early satiety, upper abdominal bloating, nausea, epigastric fullness. As dyspeptic syndrome is often caused by excessive food intake or by consumption of certain nutrients, the disease may have a severe prognosis. Hearty meals, the nature of foods, the preparation of meals, possible special conditions of eating may often contribute to dyspepsia.
Keywords: HEREDITY, INTESTINAL TRANSIT, EXCESSIVE FOOD INTAKE, DISCOMFORT, NAUSEA, BLOATING.

Dyspepsia is a condition without systemic involvement, characterized by symptoms localized in the upper abdomen and manifesting itself in epigastric pain, fullness, bloating or discomfort. Dyspepsia is characterized mostly by pain that varies from day to day, without any obvious relationship to meals or certain foods. Dyspepsia occurs as burning and cramp after an emotion or a certain mental state (1).

Dyspepsia, often called indigestion, is a common disease, often associated with the ingestion of certain foods. The dyspeptic syndrome is most commonly caused by excessive food intake or by consumption of certain foods and has a possible severe prognosis. Dyspepsia was widely considered a psychosomatic disorder, as it is due to a functional disturbance in the nervous system or in the muscular activity of the stomach or of the small intestine.

Dyspepsia has an important *epidemiological* significance, representing about 2-5% of all clinical examinations of the family doctor and 20-45% of the gastroenterologist consultations. 70-80% of patients seeking medical care for upper abdominal symptoms have no organ injuries, but functional dyspepsia, and the remaining 20-30% show systemic manifestations related to gastro duodenal ulcer, gastric neoplasm and chronic pancreatitis. Dyspepsia is thought to affect up to 46% of the population (2).

Dyspepsia can be designated as an "iceberg symptom" with a major impact on health systems, requiring special attention from both family physician and gastroenterologist, but also from decision makers of the community health system (3).

The human body is anatomically built not to consciously perceive the function of its organs. Metabolic and digestive processes are genetically programmed to develop within certain limits and to show self-regulating variations that do not reflect themselves in the consciousness. They become conscious when disturbances occur in the normal evolution of phenomena and when functional imbalances or abnormal states are present (3).

On an organic and functional level, dyspepsia is expressed by how the individual and his digestive organs react to food. Their susceptibility to food and the complex process of digestion are influenced by many factors.

Although dyspepsia affects women and men of all ages, it is more common in women aged 16 to 60 years. Women have often dyspepsia during menstruation or pregnancy. Smoking is another risk factor for dyspepsia (4).

Gastrointestinal diseases inducing dyspeptic phenomena are as follows: air intake (aerophagia); gastric juice or regurgitated gas caused by gastro esophageal reflux disease or by hiatal hernia; peptic gastric or duodenal ulcer; gastric cancer; the inability to digest milk and milk products (lactose intolerance); irritable bowel syndrome, a disorder that affects the transit of food through the intestines. The significant overlap of irritable bowel syndrome and dyspepsia may be explained by their common visceral hypersensitivity. Dyspepsia and gastro esophageal reflux overlap is caused by high somatisation, especially insomnia and medication use (e.g. proton pump inhibitors) (5).

Many non-gastrointestinal diseases are also associated with dyspepsia: diabetes, thyroid disease, hyperparathyroidism, severe renal disease, cholecystitis, anxiety or depression, side effects of caffeine, alcohol or medication.

The symptoms of dyspepsia originate in the upper gastrointestinal tract, particularly in the stomach and in the first section of the small intestine. In most cases, symptoms occur after the ingestion of food in the form of abdominal pain, allergic manifestations, eructation, bloating, burning sensation after eating, chronic irritable bowel, chronic fatigue, constipation, diarrhea, bloating, insomnia, joint and muscle pain, nausea, intestinal gurgling, vomiting.

Dyspeptic symptoms may also accompany gastritis, gastroenteritis, gastric ulcer, vesicular lithiasis, pancreatic disease. Pregnancy and advanced diabetes may also be associated with dyspepsia that however may occur without accompanying other digestive diseases.

Many studies suggest that the overlap of dyspepsia and other conditions, such as gastro esophageal reflux or *Helicobacter pylori* infection, may represent a distinct syndrome that needs different management strategies (5, 6).

Factors that may affect digestive process

Individual characters governed by heredity (presence or absence of certain enzymes, abnormal conformation of some digestive organs or segments) and the presence of a certain neuro vegetative tone, a certain combination of neuro humoral and endocrine factors are clearly involved in the process of digestion. A medical history with acute digestive diseases during child-

hood, chronic digestive diseases or digestive diseases that have required surgery, infectious diseases with digestive involvement etc, chronic abusive use of certain medications (aspirin, phenylbutazone) or coffee and alcohol abuse can lead to dyspeptic disorders (7).

There has been shown that nonsteroidal anti-inflammatory drugs, antibiotics and estrogens are commonly associated with dyspepsia.

The digestive process, especially in the modern times, when food is excessively consumed or when nervous tension is frequent, digestive disturbances occur immediately and last for days.

Abusive consumption of certain foods (meat, pasta, sweets, vegetables with high cellulose content) and other factors involved in digestion may lead to functional disorders localized in different segments of the digestive tract and manifesting as various signs and symptoms that define dyspepsia (8, 9).

Other factors that may cause or contribute to dyspepsia are intestinal obstruction, malabsorption or liver and pancreatic diseases, allergies and food intolerances.

Food that is difficult to digest and gut bacteria can produce toxins that affect the mucosal tissue and may lead to leaky gut syndrome. This condition occurs when undigested food particles which are normally eliminated in the feces pass through the structures of the intestinal lining and are absorbed by the system, causing digestive disturbances.

The factors contributing to this phenomenon are abnormal intestinal flora, food allergies, alcohol consumption, parasites, chemicals or drugs that irritate the small bowel.

Psychological factors, such as anxiety, stress or anger, may contribute to disturbance of the nervous mechanism controlling bowel and stomach muscles.

If the reason that caused indigestion remains unclear, there may be functional dyspepsia. This is a type of indigestion caused by the alteration of the capacity of the stomach to digest food, before it passes into the small bowel.

Theories on the causes of dyspepsia suggest abnormal perception at the level of the intestinal sensory nerves, followed by impaired information processing and disturbed bowel stimulation by motor neurons.

Clinical aspects

Dyspepsia may persist for years, if not the whole life time, and it manifests itself periodically and the symptoms may be more common over some days, weeks or months. The Rome II definition of functional dyspepsia describes it as the presence of abdominal pain or discomfort in the epigastria for at least 12 weeks over the last 12 months that cannot be explained by upper gastrointestinal investigation. The more recent Rome III definition requires symptoms to be present for the last 3 months, with symptoms onset at least 6 months before diagnosis (10).

When digestion is complete, the stomach empties into the upper part of the small bowel through mechanisms regulated by the brain and by a nerve network located in the muscles of the digestive tract wall. The coordination between these nerve endings that secrete neurotransmitters ensures that hormones and muscle fibers in the wall of the digestive tract regulate the movement of the digestive tract and consequently favor digestion, absorption and elimination of the ingested food.

There are three clinical forms of dyspeptic syndrome, depending on the prevalence of some of the symptoms: *reflux type* (regurgitation, eructation and retrosternal

burning are common), *ulcerative type* (characterized by epigastric pain and feeling of hunger in the stomach), *dysmotility type* (mostly colicky pains, bloating).

However, the most important symptom is *the pain*. It is generally perceived as abdominal discomfort or real pain in the whole abdomen or on the flank, under the right or left costal margin or in the epigastrium. Sometimes the pain is even perceived as cramps. The pain may have an esophageal, gastric, pancreatic, biliary or intestinal origin. The pain may be continuous, intermittent, at a certain time after meals or at night. Another group of dyspeptic symptoms is caused by excessive production of gas in the digestive tract and is manifested by eructation, flatulence, gurgling, and abdominal bloating. Patients experience sometimes loss of appetite, may lose weight and have discomfort, especially after meals. Although these problems occur, the general state of the patient is good most of the times. Of course, not all of these symptoms are found together in the same dyspeptic patient (11).

Sometimes dyspeptic phenomena are better grouped and systematized. In the intestine, carbohydrates undergo a fermentation process and proteins undergo a putrefaction process under the influence of the microbial population at this level. When meals with a lot of vegetables high in cellulose or with a lot of milk or meat are preferred and when gastric, pancreatic or biliary secretion disorders are present, associated with an increased sensitivity of the intestinal mucosa, there is a risk of *fermentation* or *putrefaction* dyspepsia with excitation of intestinal peristalsis and diarrhea. Therefore, one-sided food patterns may change the balance of intestinal bacterial flora, leading to disturbances in the activity of the small bowel and especially of the large intestine (12).

Due to the disturbance of carbohydrate digestion, *fermentation* dyspepsia is accompanied by excessive production of intestinal gases and is manifested by bloating, gurgling and flatulence. These gases are eliminated with the feces and have a pungent sour smell. Stools are light colored and with acidic reaction.

Putrefaction dyspepsia is caused by excessive growth of putrefaction proteolytic flora, due to the disturbance of protein digestion. It is manifested by pasty smelly stools with alkaline reaction. The disease is more common in persons with excessive consumption of meat and meat products, in which case the digestion and absorption of proteins is not carried out completely. They are poorly digested in the small bowel. Afterwards, they reach the colon, where they will be subjected to the action of the flora of putrefaction, irritating the wall of the colon and accelerating the transit.

In disorders of fat digestion caused by biliary pancreatic or intestinal deficiency, soap dyspepsia may occur. The patients complain of loss of appetite, abdominal fullness, eructation, bloating, abdominal cramps at about an hour after the meal. The stools contain large amounts of crystallized soap, fatty acids and fat bubbles. Malaise, various intestinal absorption disorders and intolerance or allergy to certain foods may also occur, with consequences on the general health status (13).

Aerophagia and excessive intestinal fermentation cause pain in the anterior and left thoracic region, resembling sometimes pain of heart and vessel diseases, due to the distention of the upper portion of the stomach and of the large intestine.

Clinical diagnosis of dyspepsia

Dyspepsia is diagnosed based on typical

symptoms and in the absence of other gastrointestinal diseases, in particular those related to hyperacidity and non-gastrointestinal diseases.

The dyspeptic syndrome may occur as the result of a temporary eating disorder, but when symptoms occur in a young person or they persist, worsen and disturb the daily activities of the individual, an investigation of the upper digestive tract should be made.

Indigestion is a discomfort rather than a serious problem. However, it may be a sign of a major underlying disease and it is important to be carefully investigated, especially when the onset is recent.

Laboratory investigations are needed in order to rule out other diseases, rather than to diagnose dyspepsia. They are mainly used in order to exclude the presence of other gastrointestinal and non-gastrointestinal diseases.

Additional tests include stool tests that determine whether the stomach inflammation had *Helicobacter pylori*. Upper digestive endoscopy, radiography of the esophagus, stomach and small intestine, abdominal ultrasound may also be performed. Some studies warn that inadequate work up in primary care leads to unnecessary endoscopic investigation, when the guidelines are not considered and the age of the patients might hardly be associated with the risk of malignancy (2).

For the diagnosis of functional dyspepsia, tests are necessary in order to rule out severe gastrointestinal diseases, but they are rather ineffective in identifying the cause of dyspepsia, which is caused by a malfunction of the nervous system or of the muscular activity of the digestive tract.

Initial diagnosis can be made by the family doctor through physical examination and medical history review.

Differential diagnosis is made in case of systemic disorders, irritable bowel syndrome, and lower abdomen distress, designated as a single entity called "irritable digestive tract disorder". *Evolution* and *prognosis* are favorable.

Treatment of dyspepsia

The treatment includes dietary and hygienic measures. If the symptoms persist, a pharmacological treatment to control symptoms is required (14). Therapies for dyspepsia can be subdivided depending on the underlying disease that is being treated: gastro esophageal reflux disease, peptic ulcer disease, functional dyspepsia (15).

The treatment of dyspepsia is mainly educational and prokinetic drugs and muscle relaxants are used. Antidepressants and the change of the hygienic and dietary regimen may also have a beneficial role.

If the indigestion has a specific cause (ulcer or gastritis, etc.), treating these disorders relieves the symptoms. When the cause is not identified, diet changes and administration of drugs is the most effective treatment.

The treatment of dyspepsia begins with a proper diet, adapted to gastric chemistry, intestinal motility and subjective symptoms, and with the treatment of the systemic disease that has caused dyspepsia (parasitosis, gallstones or gallbladder dyskinesia, colopathy, appendicitis, adnexitis).

Drug therapy includes antisecretory medication such as proton pump inhibitors (omeprazole, esomeprazole, lansoprazole, pantoprazole), H2 blockers (cimetidine, ranitidine, famotidine), prokinetics (metoclopramide) and antibiotics. Acotiamide is a novel prokinetic that has been shown to be effective in functional dyspepsia in a phase III randomized trial (15).

When peptic ulcer caused by *Helicobac-*

ter pylori is diagnosed, an antibiotic is also prescribed. When even a thorough investigation did not reveal a cause of the symptoms, antidepressant medication may be used, in order to alleviate the discomfort of indigestion by reducing the sensation of pain and eliminating symptoms such as headache, nausea, night sweats, restlessness and constipation.

CONCLUSIONS

Any disturbance of the normal function of the nervous system or of the muscular activity of the digestive tract can cause dyspepsia. Dyspepsia is diagnosed based on evaluation of typical symptoms and on the elimination of non-functional gastro-intestinal diseases, non-gastro-intestinal disorders and mental illness.

Excessive food intake that stresses and disturbs digestion, the disproportion between food intake and digestion capacity, hereditary or acquired individual characteristics of the digestive structures, special psychological conditions of eating may cause dyspepsia, which may be seen as an epiphenomenon of esophageal, gastric, biliary, pancreatic and intestinal diseases.

Faculty of Medicine
2. Discipline of Hygiene-Environmental Health

AGE AT INITIATION OF SEXUAL LIFE, PROTECTION AT FIRST INTERCOURSE AND SOURCES OF INFORMATION REGARDING SEXUAL AND REPRODUCTIVE HEALTH **(**Abstract): **Objectives:** this study is intended to determine: age at initiation of sexual life, protection at first intercourse and sources of information regarding sexual and reproductive health. The trends identified by this study can form the basis of public health programmes. **Material and methods:** between 2011 and 2012, 564 subjects, 18-35 years old, from urban and rural environment, have responded to a questionnaire with 96 items on family-related topics. In the present study we focused on three items. The Pearson chi-square tests were employed using the statistical programs *SPSS*. **Results and discussion:** most of the subjects had engaged in their first intercourse at 17–18 years old (48.58%). The number of individuals who had started their sexual life earlier than at 17 years of age was higher in males and in young subjects ($p<0.001$). The protection at first intercourse was very low (38.4%) and the condom was the main method (34%). The protection was significantly higher in urban environment and in case of people with average and high educational level ($p<0.001$). As for the information on the subject of sexual behavior, the smallest contribution came from doctors and sanitary staff (12.6%), from the school (15.2%), from parents, relatives (17%). Friends and acquaintances contributed to the largest extent - 45.7%, and the contribution of Internet was 41%. **Conclusions:** Diminishing the pregnancy rate in teenagers and the unwanted pregnancy rate, as well as the rate of sexually transmitted infections, requires a multidisciplinary approach in the prevention programmes. The school and parents are crucial factors within the education programmes. **Keywords:** FIRST INTERCOURSE, CONDOM USE, SEXUAL AND REPRODUCTIVE HEALTH, SEX EDUCATION

Early initiation of sexual activity can have multiple risks such as: cervical cancer, breast cancer, early aging, infertility, infection with Human Immunodeficiency Virus (HIV) and other sexually transmitted infections **(**STIs). The youth who start their sexual life too early are in danger of having more sexual partners, of using condoms to a lesser extent and of engaging in other health risk behaviors, such as: alcohol consumption, smoking, drug consumption, delinquency, violence (1, 2).

The age of beginning sexual life is determined by biological aspects such as menarche and pollution, but especially by culture, environment, society, and the

world in which the individual lives. Religious education, religious belonging, their history and the constitutional provisions or the supplementary legislation regarding Church have a more or less important influence on the sexual and reproductive behavior (3, 4, 5).

The sources of information have an important role in the formation of the concepts of sex, sexuality, gender and in the development of sexual behavior.

In 1990, after the collapse of Communism and the establishment of a democratic regime, the health of women and children was very precarious, which imposed since 1993 the launch of public health programmes and strategies for family planning by modern means of contraception, the improvement of neonatology services, for the control of STIs and HIV, for the screening for genital and breast cancer, for sexual education etc. Unfortunately, since 2006, Romania has not had any national strategy in the field of health, sexual rights and reproduction. As a result of the precarious presence of national programmes of prevention and education on SRH, as compared with western European countries, Romania reports one of the highest incidence of Cervical Cancer and one of the highest rates of diagnoses of syphilis (6, 7).

Taking into consideration the facts presented above, this study aims at the determination of: age at initiation of sexual life, protection at first intercourse (FI), sources of information regarding sexual and reproductive health (SRH), and impact of social-demographic variables on these items in Romania. The trends identified by this study regarding sexual activity and the sources of information in the field of sex can form the basis of public health programmes which are targeting the SRH.

MATERIAL AND METHODS

Design and sampling, setting of the study. This research was conducted using a cross-sectional study with quantitative data. The sample, which is not representative for the whole country, includes N=564 subjects. The distribution of the subjects was relatively homogenous with respect to environment, gender, educational level, and age (tab. I).

TABLE I

Distribution of subjects according to environment, gender, educational level and age group (socio-demographic characteristics)

Social-demographic characteristics	Number	%
Environment		
Urban	317	56.2
Rural	247	43.8
Gender		
Male	265	47.0
Female	299	53.0
Educational level		
Low (primary education <10 years)	158	28.0
Medium (secondary education 10–12 years)	229	40.6
High [a]	177	31.4
Age groups (years)		
18–26	317	56.2
27–35	247	43.8

Legend: [a]·Tertiary education >12 years, completed by obtaining a diploma. University diploma. Post-university diploma

The study was conducted between 2011–2012 in urban areas within Bucharest, Craiova and Satu Mare; it was also carried out in the villages of Cioroiaşi and Stolnici and in villages in the county of Satu Mare.

Informed written consent was obtained from each participant at recruitment. The subjects were informed that they could withdraw from the study at any stage and they were assured of confidentiality. The study was approved by the Ethics Commission of the "Francisc I. Rainer" Anthropology Institute of the Romanian Academy.

Questionnaire design, data management and statistical analysis. We used an *omnibus* questionnaire of 96 items that focused on topics related to family functioning: domestic economics, education, cohesion & solidarity and sexual reproduction (8). In the present study we focused on three items: age at FI, protection at FI, sources of information regarding SRH. The Pearson chi-square tests were employed using the statistical programs *SPSS (SPSS* Inc., Chicago, IL). Demographic variables used in the statistical analyses were: environment, gender, educational level and age group.

RESULTS

***First intercourse*.** At the moment of investigation, a number of 15 subjects (2.7%), of which 13 women, had not started their sexual life. Among the 549 subjects who had started their sexual life, most of them, 48.58% (N=266), had engaged in the first intercourse at 17–18 years old. The ratio of those who had started their sexual life between 15–16 years old was 21.1%, and those who had had FI between 13–14 years old amounted to 5%. In the whole sample, the average age at the initiation of sexual life was 17.67 years, median 17 years with a minimum of 13 years, a maximum of 30 years. The average age at FI was higher in the urban environment (17.84 years in urban vs. 17.46 years in rural area) was higher for women (18.08 years females vs. 17.23 years males), for individuals with a higher educational level (18.19 years in high-level education subjects vs. 17.44 years in subjects with low level of education). The average age of virginity loss decreases with the age of the respondent; the average age at the start of sexual life in the lot born between 1976 and 1984 was 18.41, and in the lot born between 1985 and 1993 it was 17.07 years. The ratio of the individuals who started their sexual life at an age earlier than 17 years was higher in men ($p<0.001$). Those with medium and high levels of education tend to begin sexual life at an age higher than 17 years ($p=0.015$). The ratio of the individuals who started their sexual life earlier than at the age of 17 years is higher in young subjects, ranging between 18-26 years old ($p<0.001$) (tab. II).

Protection at first intercourse. The protection at FI was very low, only 38.4% (N=211) of the 549 subjects who had started their sexual life used protection. Condoms were the main protection method at FI, namely 34% (N=192). The protection was significantly higher in individuals from urban environment ($p<0.001$) and in those with average and high educational level ($p<0.001$) (tab. III). Both men and women, in similar proportions, used no protection at all against STIs or pregnancy at their FI.

TABLE II

Distribution of subjects by groups of age at FI, according to gender, educational level and age groups

Age groups at FI	Gender*		Educational level**			Age groups (years)*	
	Male	Female	Low	Medium	High	18-26	27-35
<=15	74.6	25.4	32.2	39.0	28.8	61.0	39,0
16–17	51.7	48.3	27.8	46.1	26.1	71.7	28,3
18–19	39.0	61.0	28.6	39.6	31.9	46.7	53,3
>= 20	37.2	62.8	24.4	26.9	48.7	20.5	79,5
Total	47.9	52.1	28.1	40.4	31.5	55.0	45

Sources of information on sex. To the information on the subject of sexual behavior, the smallest contribution came from doctors and sanitary staff (12.6 %), from the school (15.2), from parents, relatives (17%). Friends and acquaintances contributed to the largest extent – 45.7% - to supplying information on the topic of sexual behavior; then followed the mass-media and the Internet with a contribution of 41%, and specialized books with 24.3%. In most cases, subjects from urban environment, women, and people with average and high educational level received to a greater extent information from all sources (tab. IV).

DISCUSSION

First intercourse. Many teenagers who started their sexual life earlier, without being ready for it, had regrets and did not really enjoy that unique experience. Most of them acted under the psychological pressure of peer group norms, to be accepted and valued (9).

When comparing the data of an American study conducted on teenagers which the prevalence of early sex, defined as having one's first sexual intercourse before age 14, a much lower prevalence is obvious for Romania (more than one third in the American study vs. 0.4 % in the present Romanian study) (10). Just like other studies, this study shows that women have waited longer before having their first sexual experience (11). This could be explained by the following aspects: Young men are encouraged to lose their virginity and to have as many sexual partners as possible as a sign of virility and manhood. On the contrary, girls are encouraged to postpone as much as possible the moment of their first sexual act, to have a small number of partners as a proof of sobriety and obedience.

Just like other studies, we identified a change of patterns of sexual activity by lots of age (12, 13). The lot born in the interval 1985-1993 started sexual life at an average age lower by almost one and a half years as compared to the lot born between 1976 and 1984.

Protection at first sexual intercourse. In Romania after 1990 it was possible to legally use modern means of contraception. So, those who were born in 1976, being 35 years old in 2011, when the data were collected, possibly starting their sexual life at the age of 13, had every possibility to practice protected sex. The ratios of subjects who did not use any protection at FI (61.6%) are alarmingly high. When comparing the studies conducted in Romania: Reproductive Health Survey Romania, 1999 (RHSR 1999), Reproductive Health Survey Romania, 2004, and the Study Rada–Tarcea (2005–2006) (14, 15, 16), the present study shows that the prevalence of using the condom in the population between 18-35 years old has slightly increased.

There are studies which identified that potential condom users raised the question that the condom could reduce the pleasure of sexual intercourse (17, 18). Therefore, one of the methods of encouraging protection could be the stronger highlighting of advantages and positive consequences in the long run of using the condom with occasional partners, as against the risks of unsafe sex. At the same time, it is necessary to make men responsible with respect to SRH and to educate women to negotiate the use of condom.

Sources of information on sex. Just like other studies (19), in this study it has

been found that friends and acquaintances contributed to the largest extent to the information on the subject of sexual behavior. Pertinent sources such as school, doctors, sanitary staff, are very poorly represented. Almost half had mass-media as a source of information. In comparison with the Romanian study RHSR 1999, we have identified an increase of the contribution of doctors and mass media and a decrease of the contribution of friends and acquaintances. E-health (healthcare, offering health-related information by Internet) must be regarded as an opportunity of improving the healthcare services. The greatest challenge for e-health is the accuracy and reliability of information. Internet is teeming with inaccurate, incomplete information which can lead to making wrong decisions (20).

In Romania, after 1990, volunteers were trained by international agencies and non-governmental organizations which taught in high schools lessons about the health of reproduction, family planning and STIs. Starting with the school year 2004-2005, the optional subject Education for Health was introduced in the curriculum for grades I–XII (21). Unfortunately, in the school year 2011-2013, only a few of the students attended classes for this subject matter.

Parents can play an important role in protecting youth against risky sexual behaviors, especially if they are well informed. The studies show that when parents discuss with their children about SRH and when they monitor their behavior, young people are less likely to exhibit a risky behavior, both in general circumstances and in sexual matters in particular (22).

In this study, communication with parents on questions relating to sexual and reproductive health was very scarce.

CONCLUSIONS

The results of the study show that Romania, just like other ex-Communist East-European countries, has caught up with the western countries as to the issues of sexual behavior. The main issues are a poorer implementation rate of the education for SRH, and insufficient dealing in education and teaching with the psychological and emotional elements of a relationship.

As for behaviors with risk for SRH, such as FI with no protection, and age of FI 17 years or less, it has been ascertained in the rural environment, in men and in those with low and average educational level. As compared to the oldest studies conducted in Romania, the present study shows only a slight improvement of obtaining information on sex from specialists in the field, from school and parents. For diminishing the pregnancy rate in teenagers and the rate of unwanted pregnancies, as well as the STIs rate, a multidisciplinary approach is required in the prevention programmes. Both school and parents are crucial factors in this extensive undertaking within the education programmes for SRH.

NEWS

LYMPHOPROLIFERATIVE CONDITIONS OF THE SEROSA

A diverse and complex variety of lymphoproliferative diseases may involve the serosa, with widely differing clinical outcomes encompassing a spectrum of benign and malignant conditions. The World Health Organization classification of hematologic malignancies recognizes each disease by distinct clinical, morphologic, immunohistochemical, and genetic features. Accurate diagnosis commences with the morphologic interpretation but also requires numerous sophisticated tests such as immunohistochemistry, flow cytometry, molecular genetic clonality studies, and molecular cytogenetics (eg, fluorescence in situ hybridization). All forms of hematologic malignancy may involve the various serosal sites, although this is usually observed as secondary involvement in persons with known lymph nodal, marrow-based, or extranodal disease. Primary pericardial, pleural, and peritoneal lymphomas are rare. Many nonneoplastic conditions may mimic lymphoma and a variety of nonhematolymphoid tumors may simulate hematologic malignancies. An understanding of the role of ancillary tests, together with an appreciation of their limitations, will prevent misdiagnosis (Richard Attanoos. Lymphoproliferative Conditions of the Serosa. *Arch Pathol Lab Med*. 2012;136:268–276).

ROMANIAN BLOOD DONORS SCREENING: IS IT REALLY NECESSARY AND/OR MANDATORY?

ROMANIAN BLOOD DONORS SCREENING: IS IT REALLY NECESSARY AND/OR MANDATORY? (Abstract): Blood services are required to provide the safest possible products, but no transfusion can ever be totally free of the risk of transfusion transmissible infections (TTI). Over the past decade, the risk of TTI through transfusion has been reduced (e.g. 1 in 300 000 for HBV to 1 in 2 million for HIV). With the introduction in 1999 of sensitive and expensive nucleic acid testing (NAT) technology in some countries, the disease transmission rate and the window period have been significantly reduced, but a remaining concern is the chance that a blood donor will be infected and not detected by such tests. To obtain safe blood and blood components it is important to ensure that the donors are healthy and free from TTI by using a donor selection procedure meticulously made, using a donor questionnaire to assess donor health and safety and for reducing the risk of transmission of infection, in particular for infections for which no suitable screening tests are available. In Romania the prevalence of TTI among donor population is high in comparison with other European Union (EU) countries. This may require significant improvements in the screening process of both donors and donations to minimize the infectious risk. **Key words**: BLOOD DONATION, TRANSFUSION TRANSMISSIBLE INFECTIONS, SCREENING

Worldwide, more than 92 million blood donations are collected annually. The demand for blood and its components is increasing and there is a need for more donors to be recruited and retained. An estimated 1.6 million units are discarded annually due to the presence of infectious markers for transfusion transmissible infections (TTI).

In developed countries, blood transfusion or plasma-derived products have been the main route of HCV transmission. Zero risk, which has been the goal, has yet to be achieved. False negatives still persist and transmissions of transfusion transmissible viruses still occur, although rarely (1).

In all south-eastern Europe countries, including Romania, the prevalence of TTI among donor population is high in comparison with others European Union (EU) countries (tab. I) (2).

A study performed by Brumboiu *et al* in 2003-2010 (submitted), in blood donors from Cluj and Satu Mare, two counties of the North West region of Romania, describes a higher seroprevalence for HCV in comparison with other studies (3).

Donors are our essential partners in ensuring a safe and adequate blood supply (4).

The difficult question is how to balance the burdening of the donor, faced with an

increasing number of very private questions, with the voluntary character of donating blood (5).

WHO. Blood services in south-eastern Europe:Current status and challenges. 2007

This paper aims to summarise the necessity and possibility of minimizing the infectious risk in order to assure safe blood products in Romania.

Transfusion transmissible infections (TTI)

While in the past, the risk of transfusion-transmitted infections (TTI) was accepted by patients and physicians as unavoidable, a low-risk blood supply is expected today. Since the early nineteen sixties, blood banks, as well as plasma manufacturing industries, have aggressively pursued strategies to reduce the risks of TTI (6).

The magnitude of the TTI varies from country to country, depending on TTI's load in that particular population from where blood units are sourced. 7 There is a long list of viruses, parasites and bacteria which can be transmitted through blood transfusions. Among them, from far the most important TTI are human immunodeficiency virus (HIV-I/II), hepatitis B virus (HBV), hepatitis C virus (HCV), syphilis and transfusion-associated malaria infection.

Given the potential transmission of viruses during the 'immunological window period' [i.e. the period of early infectivity when an immunologic test is non-reactive], novel non-serology based approaches such as viral nucleic acid testing (NAT) have been established (6).

Today, the residual risk of TT HBV infection varies between 0.75 per million blood donations in Australia, 3.6 – 8.5 in the USA and Canada, 0.91 – 8.7 in Northern Europe, 7.5 – 13.9 in Southern Europe up to 200 per million donations in Hong Kong, largely reflecting the global epidemiology of HBV. The estimated risk for HIV transmission to date is between 0.14 – 1.1 and for HCV between 0.10 – 2.33 per million units transfused (6)

Table II describes the trends and prevalence of markers for HBV, HCV, HIV and HTLV I in Romanian blood donors from 2000 to 2004 (2).

Observations:
(*) - Only one case of HIV-2 has been confirmed in a FTBD.
(**) - Only HTLV-I but no HTLV-II has been confirmed.

WHO. Blood services in south-eastern Europe:Current status and challenges. 2007

Although the risk of transfusing a blood unit collected during the window period may be decreased using NAT, the actual benefit in most populations has first to be determined and should be balanced against

the complexity and high cost of performing NAT, including the infrastructure required. The potential benefit of detecting early infections and preventing possible transmissions of infection should be assessed in relation with the incidence and prevalence of infection in the blood donor population, the effectiveness of the blood donor selection process, the sensitivity of the serological screening currently undertaken and the ability to enhance this through (8).

Donor Selection

The purpose of donor selection is to assess the suitability of an individual to be a blood donor and that the blood products derived from this donation are safe for the recipients. Donor selection is designed to identify high risk volunteers and defer them from donating blood. 9It became clear that non-remuneration of donors is an important criterion to avoid high risk donors; this is the main reason why efforts have been made to promote a volunteer unpaid donor system in various countries in the world (5).

The promotion of voluntary non-remunerated blood donation in Romania is included in the current legislation of the blood service, but voluntary paid donors are still present in the country, 79% remunerated vs. 21%-non-remunerated donors (2).

By law, voluntary ”remunerated” donors receive one day of holiday, free admission to health care services and food tickets (2). An inadequate stock of blood usually forces transfusion service officials to turn to replacement or possibly ‘‘hidden’’ paid donors which might ultimately increase safety risks attributed to these types of donations (10)

It is known that individuals cannot objectively assess their own level of risk. Extensive questioning of all donors on their sexual behaviour could lead to a loss of existing donors who may find the process intrusive. 11 A study realized in 2012 in Cluj Blood Transfusion Centre highlights that the existing routine screening methods used in the selection process of blood donors cannot detect all risk factors for blood borne infections, particularly the sensitive behavioural risk factors (drug use, sexual promiscuity) (12).

One of the most debated issues is the definite deferral of men who had sexual contacts with other men (MSM) (even if it was once in their life), whereas heterosexual individuals are excluded for only one year after a one time risk for HIV infection. 11,13Van der Bij *et al* described that donors infected with HIV often reported male-to-male sex and a high proportion reported other sexual risk behaviours, such as anonymous sexual contacts.

Although some of this risky behaviour was associated with MSM, which is a permanent deferral for donating, more attention could be given to sexual risk behaviours in donor screening (14).

Ramezani and co-workers describe that among rejected unemployed donors the most common risk factor found was unsafe sexual conduct, which confirms that acquiring answers to standard questions from blood donors can prevent the transmission of blood-borne infectious diseases (15).

Another issue is that many donors either do not understand transfusion-related risks or they do have knowledge on transmission routes but believe it doesn’t apply to them. For example, a large proportion of HCV infected donors has a history of injecting drug use but deny such use at the time of screening for blood donation. People who have used and stopped using drugs in the past might not consider themselves as “addicts” or might even believe that their past injecting drug use is not harmful for the safety of the blood they now wish to donate

(14).

Hepatitis C was found mostly among intravenous drug users and their spouses, probable virus carriers and donors with a history of unsafe sexual contact (15). In Cluj blood donors population no intravenous illicit drug use was reported (12).

The key to minimize the infectious risk is the screening of both donors and donations. Screening is thus a two-stage approach: the donor selection process is the first stage of the process and laboratory testing represents the second stage (14, 16). This strategy is used to protect the supply excluding the high-risk and potentially infected donors by selection and laboratory screening the donated blood. After the systematic selection and screening of donors, the residual risk of transfusion-transmitted HCV is very low nowadays.

A study carried out in the Netherlands in 2006 found a significant correlation between blood-borne infectious diseases and high risk behaviour (9,15).

Donor selection appears to be an efficient and cost-effective way to reduce the risk of TTI to an acceptable level because high risk donors mirror a high incidence rate of TTI (17).

Donors Questionnaire

The donor questionnaire is the key tool in donor selection, being designed to protect potential donors who may be at risk for an adverse consequence of blood donation and to enhance recipient safety (13).

The screening of blood donors in Romania includes a donor self-deferral questionnaire, an interview with the responsible physician, investigating each donor for possible risk behaviour for TTI and laboratory testing used to ensure the safety of the blood supply. If a screening test sample is reactive, the donation will be discarded and more specific confirmatory testing will be asked. In most cases, even if the result of confirmatory testing is negative, donors are permanently deferred; however, in some countries, re-entry algorithms are permitted with certain donor retesting protocols (13).

Along with data collected during this screening process, each individual donor confirms by signature, that he or she has fully understood all the risks that would defer him or her from blood donation. The physician examining the donor qualifies him or her as eligible to donate blood, respecting the established criteria for donor selection, or defers the donor, thus protecting the safety of the blood stock and its potential users. In addition, all the collected blood units undergo laboratory testing for human immunodeficiency virus, hepatitis B virus, hepatitis C virus and syphilis.

The questionnaire is the only line of protection against certain infections for which no testing is performed, such as malaria, babesiosis, leishmaniasis, and Chagas disease (13).

Certain questions aim to identify recently infected individuals who may be undetectable by currently used screening tests (window-period donors). For example, donors are asked if they have had a tattoo or a needle stick injury in the last 12 months. Other questions aim to reduce the number of prevalent infections, in part to offset testing and inventory release errors or lack of test sensitivity. For example, intravenous drug users are permanently excluded from blood donation. (13).

It is unclear if individuals currently deferred for MSM behaviour would consider additional questions about behaviours specifically addressed to them as being discriminatory or as being a positive development in identification of a low-risk group that would then be allowed to donate (4).

The use of a donor questionnaire prompts donor selection staff to ask im-

portant questions and carefully assess the donor's health. By presenting all relevant information in a standard format, a donor questionnaire facilitates decisions on the acceptance or deferral of the donor.9 However, individuals who do not respond accurately or truthfully to the questionnaires about infectious disease risk factors at the time of screening represent a potential threat to the safety of the blood supply due to enhanced risk for window-period infections. There are donors, who had donated primarily to receive the results of an HIV test and nearly 25% thought it was reasonable to donate to be tested for HIV, and that 12% believed that donating with known risk factors is acceptable (5).

The decrease in HCV seroprevalence in blood donors observed in other studies was not present in the study performed by Brumboiu *et al.*, where the prevalence evolution trend was stable. Such trend may reflect the HCV prevalence in the general population, the need for maintaining the same methods for donors' selection 3 and at the same time the necessity of educating donors on transfusion-related risks and transmission routes for TTI.

CONCLUSIONS

In most countries - Romania included - it seems difficult to keep a balance between the increasing demand for blood and the need to recruit and retain more donors. What stays the most important is to ensure safe blood supply by excluding high risk donors. The assessment of the donor's health and TTI risks requires a sensitive, non-judgemental approach to ensure confidentiality (9).

Most blood donors perceive themselves to be healthy, but some are unsuitable to donate blood. Additional time and effort should be spent by the trained personnel who interview the donors to explain why all very private questions are necessary.

The process of selecting blood donors based on their potential exposure to transmissible diseases is not always simple and straightforward, nor is it always strictly and / or exclusively based on scientific and epidemiologic data (4).

NEWS

PERINATAL CHARACTERISTICS AND BREAST CANCER RISK IN DAUGHTERS

Authors from Divisions of Cancer Epidemiology and Genetics, National Cancer Institute, in a paper published in Journal of Developmental Origins of Health and Disease, highlighted that the *in utero* origins of breast cancer are an increasing focus of research. However, the long time period between exposure and disease diagnosis, and the lack of standardized perinatal data collection makes this research challenging. Authors assessed perinatal factors, as proxies for *in utero* exposures, and breast cancer risk using pooled, population-based birth and cancer registry data. Birth registries provided information on perinatal exposures. Cases were females born in Norway, Sweden or Denmark who were subsequently diagnosed with primary, invasive breast cancer (n=1419). Ten controls for each case were selected from the birth registries matched on country and birth year (n=14,190). Relative risks (RRs) and 95% confidence intervals (CIs) were estimated using unconditional regression models. Breast cancer risk rose 7% (95% CI 2-13%) with every 500 g (roughly 1 S.D.) increase in birth weight and 7% for every 1 S.D. increase in birth length (95% CI 1-14%). The association with birth length was attenuated after adjustment for birth weight, while the increase in risk with birth weight remained with adjustment for birth length. Ponderal index and small- and large-for-gestational-age status were not better predictors of risk than either weight or length alone. Risk was not associated with maternal education or age, gestational duration, delivery type or birth order, or with several pregnancy complications, including preeclampsia. These data confirm the positive association between birth weight and breast cancer risk. Other pregnancy characteristics, including complications such as preeclampsia, do not appear to be involved in later breast carcinogenesis in young women. (Troisi R, Grotmol T, Jacobsen J, et al. Perinatal characteristics and breast cancer risk in daughters: a Scandinavian population-based study. *J Dev Orig Health Dis.* 2013; 4(1):35-41)

NECROTIZING ENTEROCOLITIS, A RARE BUT SEVERE CONDITION WITH INSIDIOUS POSTOPERATIVE COMPLICATIONS

C. Bălălău[1], I. Motofei[1], S. Voiculescu[2], F. Popa[1], R.V. Scăunaşu[2]
University of Medicine "Carol Davila" – Bucharest,

1. "St. Pantelimon" Emergency Universitary Hospital
2. "Coltea" Universitary Hospital

Necrotizing enterocolitis, a rare but severe condition with insidious postoperative complications(Abstract): Necrotizing enterocolitis (NEC) is one of the most frequent causes of gastrointestinal perforation in premature neonates, only few case series and reports being described in adult patients. Early in the course of the disease, superficial mucosal ulceration, sub mucosal edema and hemorrhage occur. Further progression leads to transmural necrosis leading sometimes to bowel perforation. Six cases encountered in our clinic in recent years led us to resume discussions on necrotizing enteritis, not because it is a rare disease, but due to the severe postoperative complications. **Material and methods:** Our lot consisted of four stage 1 patients and two with Bell stage III NEC and severe intestinal injury, necrosis, and perforation. All of the patients were diagnosed preoperatory with other surgical conditions, like appendicitis with peritonitis, perforated duodenal ulcer or acute cholecystitis. **Results**: We present to review two cases. For patients undergoing laparotomy, resection of the involved intestine mandates either enterostomy formation or primary anastomosis. An intermediate option is laparotomy with intestinal resection and delayed anastomosis 48 to 72 hours later. Because of the small number of patients in our lot, we cannot advise a certain surgical treatment, but a strategy involving bienterostomy*per primam* should be further analyzed. The choice of operative intervention reflects multiple variables, including age, physiologic status, institutional resources and surgeon preference based on experience. Primary peritoneal drainage for perforated NEC may help to resuscitate and treat a critically ill patient initially, and in some instances, may be definitive operative intervention. **Conclusions**: Relatively rare disease, of unknown etiology and elusive pathogenesis, NEC has initial non-specific symptoms and clinical features that mimic more common surgical diseases. There is considerable controversy regarding which procedure is preferable. Currently, in the absence of rigorous evidence supporting the superiority of one approach over the other, surgical intervention depends mostly on the treating institution or the individual surgeon. **Keywords:** ENTEROCOLITIS, LAPAROTOMY, PERFORATION.

Necrotizing enterocolitis (NEC) is one of the most frequent causes of gastrointestinal perforation in premature neonates, only few case series and reports being described in adult patients. Relatively rare disease, of unknown etiology and elusive pathogenesis, has initial nonspecific symptoms and clinical features that mimic more common surgical diseases.

Due to the multifactorial nature of the

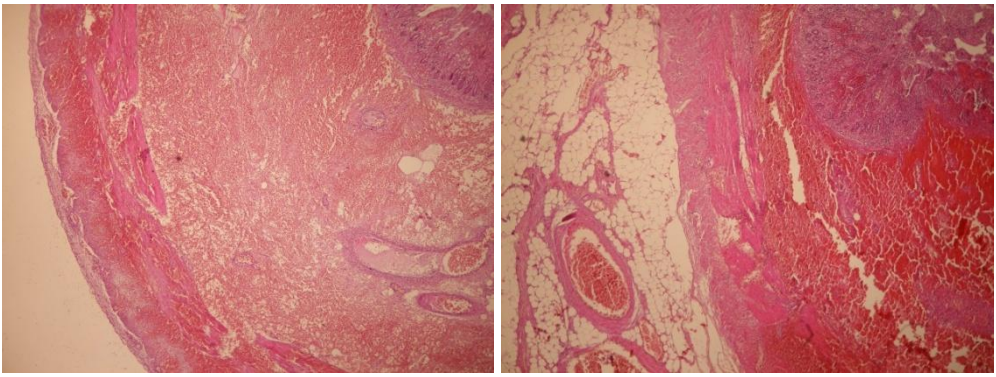
disease and limitations in disease models, NEC remains, above all, a problem of diagnosis and treatment, being accompanied by severe complications in evolution.

It is characterized by diffuse ulceration and necrosis of the distal small bowel and the colon, leading to perforation of the bowel, followed by high morbidity and mortality.

Although the exact etiology and pathogenesis of NEC remains elusive, it is well established that several bacterial and viral species have been associated with outbreaks of NEC (*Clostridium spp.*, *Klebsiella spp.*, *Staphylococcus epidermidis*, *Escherichia coli*, Rotavirus) (1). No single pathogen has been identified as causative and the ability of the microflora to colonize the epithelium and to ferment unabsorbed nutrients may be more important than the strain itself (2, 3).

Perforation seems to be caused by enteral acute ischemia due to quickly installed obstruction of the parietal microcirculation, strictly limited to the intestinal wall, without mesenteric involvement (4).

The ileum and proximal colon are the most commonly affected sites in NEC although any segment of the gastrointestinal tract can be involved including the stomach. Severity of bowel wall necrosis ranges from a small localized mucosal necrosis of a segment to transmural necrosis of the entire small intestine and colon in most severe cases (5).



a. **b.**

Fig. 1 a, b. Hemorrhage and transmural necrosis ("Sf. Pantelimon" Anatomopathological Laboratory)

In more advanced stages of NEC, pathological findings include gastrointestinal bleeding, inflammation, bacterial overgrowth, intestinal distension with multiple dilated loops of small bowel, pneumatosis-intestinalis, intestinal perforation, necrosis, hypotension, septic shock, pneumoperitoneum, and intra-abdominal fluid (6).

Six cases encountered in our clinic in recent years led us to resume discussions on necrotizing enteritis, not because it is a rare disease, but due to the severe postoperative complications (fig. 1 a, b).

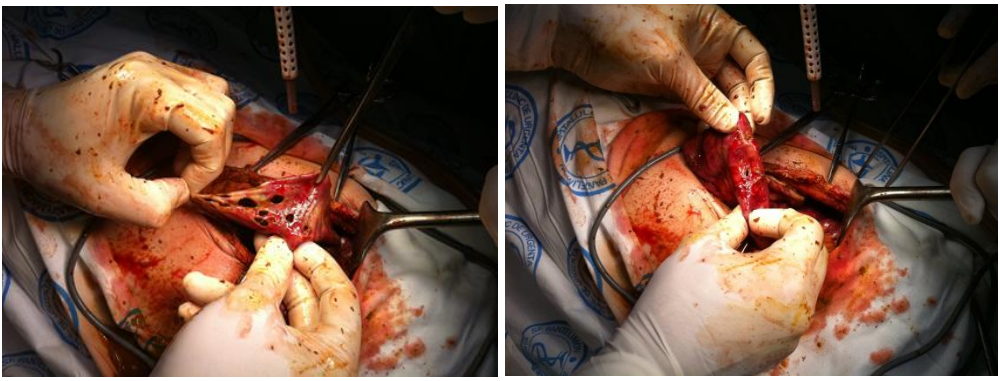
CASE REPORTS

First case, a man (MI aged 39 years) was admitted to the emergency room with the diagnosis of duodenal penetrating ulcer and pancreatitis. Admission status is marked by pallor and hypotension, severe

abdominal pain in a patient with grade II-III obesity.

First 12 hours of evolution are followed by shock, upper abdominal pain exacerbation and signs of peritoneal irritation requiring intervention (cholecystectomy for acute cholecystitis).

Due to multiple hydroaeric levels on Rx and bloating, reintervention was required for early postoperative ileus.



a. **b.**

Fig. 2 a, b. Enterectomy with termino-terminal anastomosis

Intraoperative: ecchymotic, thin-walled intestinal loops and multiple mesenteric lymph nodes. A jejunal segment of about 30 cm of necrosis and multiple perforations, blocked by the great omentum were discovered (fig. 2 a, b).

Starting at 6 days after reoperation follows a series of other 4 reinterventions imposed by anastomotic fistulas or perforations distant to the anastomosis.

The sixth intervention unveils both anastomotic failure and necrosis of afferent intestinal loop, requiring bienterostomy with Pezzer and Folley catheterization of intestinal ends. Enteral nutrition is used for the next 40 days, until complete extinction of peritonitis phenomena is achieved. A new reintervention with reintegration and anastomosis results in slow, favorable outcome with complete healing.

Second case also has special clinical features. Patient D.L. aged 15 years, was admitted for symptoms of acute appendicitis. Surgical intervention reveals acute catarrhal appendicitis for which appendectomy and drainage is performed. From the 5th postoperative day symptoms worsen and diffuse abdominal pain, bloating, lack of intestinal transit and fever require reintervention under the suspicion of peritonitis by cecal fistula. Laparotomy unveils generalized peritonitis with micro perforations of ileum in a 40 cm area, for which enterectomy and subsequent termino-terminal anastomosis are performed.

At the 11-day postoperative relaparotomy uncovers anastomosis failure and, in addition, an area of necrosis on jejunal loop, compelling right hemicolectomy and cuneiform resection of jejunal necrosis. After a couple of days, a new jejunal fistula required enterectomy and reanastomosis.

DISCUSSION

The main factors responsible for the development of NEC are intestinal ischemia

and bacterial infection. Although the etiology still remains unclear, the common organisms implicated are bacteria like *Klebsiella spp., E. coli, Enterobacter spp., Pseudomonas, Clostridium spp.,* and *Staphylococcus epidermidis*. It occurs most often in the areas of the bowel, where the blood flow from the major mesenteric arteries overlaps (7).

Early in the course of the disease, superficial mucosal ulceration, sub mucosal edema and hemorrhage occur. Further progression leads to transmural necrosis leading sometimes to bowel perforation. The clinical presentation include; abdominal distension, bilious vomiting and bloody diarrhea (5).

NEC can be classified clinical and radiological into 3 stages, as proposed by Bell and later modified by Walsh and Kliegman (5).

Stage 1 consists of non-specific clinical and radiological signs (fever, abdominal distension, dilated loops on X-ray and bowel thickening). Despite the presence of intestinal necrosis and perforation, pneumoperitoneum may not be observed. Stage 2 is characterized by blood in the stools, metabolic acidosis and classical signs of intestinal pneumatosis on X-ray. In stage 3, patients present with hypotension and shock, disseminated intravascular coagulation, occasionally peritonitis and sepsis.

Our lot consisted of four stage 1 patients and two with Bell stage III NEC and severe intestinal injury, necrosis, and perforation. All of the patients were diagnosed preoperatory with other surgical conditions, like appendicitis with peritonitis, perforated duodenal ulcer or acute cholecystitis.

Traditional surgical management of intestinal necrosis relies on the principles of controlling the source of peritoneal contamination by laparotomy, exploration of the intra-abdominal viscera, and excision of the involved, necrotic intestine.

Management options include: aggressive perioperative resuscitation, often including inotropic support; expedient and minimal operative behavior with attempts at limiting physiologic insult; evaluation of the entire intestine with resection of only necrotic or perforated bowel; enterostomy proximal to intestine of questionable viability; and preservation of the ileocecal valve if possible (8).

The choice of operative intervention reflects multiple variables, including age, physiologic status, institutional resources and surgeon preference based on experience.

For patients undergoing laparotomy, resection of the involved intestine mandates either enterostomy formation or primary anastomosis. An intermediate option is laparotomy with intestinal resection and delayed anastomosis 48 to 72 hours later.

Finally, primary peritoneal drainage for perforated NEC may help to resuscitate and treat a critically ill patient initially, and in some instances, may be definitive operative intervention.

There is considerable controversy regarding which procedure is preferable. Currently, in the absence of rigorous evidence supporting the superiority of one approach over the other, surgical intervention depends mostly on the treating institution or the individual surgeon.

These are studies that suggest that the type of operation performed for perforated necrotizing enterocolitis does not influence survival or other clinically important early outcomes in preterm infants (8).

Because of the small number of patients in our lot, we cannot advise a certain surgical treatment, but a strategy involving bien-

terostomy*per primam* should be further analyzed.

Necrotizing enterocolitis is a severe inflammatory disorder of the intestine and a major cause of death and morbidity. In contrast to medicine improvement during the past 30 years, the mortality rate of 30 to 50 percent for patients with intestinal perforation due to necrotizing enterocolitis remains essentially unchanged (9).

RADICAL RETROPUBIC PROSTATECTOMY - INITIAL EXPERIENCE (Abstract): **Aim:** To evaluate our experience with the first cases of radical retropubic prostatectomy and to use the results for patient counseling and optimizing therapeutic decision. **Material and Methods**: In the interval January 2011 - December 2012, 23 patients aged 56-69 years (mean age 62.6 years) were treated by radical retropubic prostatectomy. The retrospective study included an analysis of the significant data in the case records, surgical protocols and outpatient postoperative check-ups, special attention being given to indications, intra- and early postoperative complications (within 30 days) and hospital stay. **Results:** Preoperatively, prostate specific antigen (PSA) ranged between 4.5 and 27.2 ng/ml (mean 9.5 ng/ml), and Gleason score was 5 in one patient, 6 in 20, and 7 in 2 patients. Clinical stage was T1 in 5 patients (21.7%), T2 in 16 (69.6%) and T3 in 2 (8.7%). Mean intraoperative blood loss was 1214 ml (range 400-2500 ml), and 17 patients received blood transfusions. Postoperative complications included acute renal failure and extravasation of contrast medium during retrograde cystography in 3 cases each, urinary infection in 4 patients and wound dehiscence in 1 case. The average postoperative hospital stay was 19.57 days (range 13-43). **Conclusions:** Radical retropubic prostatectomy is a safe technique, involving a reduced risk of complications. For most patients with localized prostate cancer, radical prostatectomy is the best treatment option. **Keywords**: PROSTATE CANCER, RADICAL PROSTATECTOMY, COMPLICATIONS.

Of the therapeutic options in localized prostate cancer (PC), radical retropubic prostatectomy gives patients the best chance of survival. However, despite improvement in surgical technique (the so-called anatomic variation or with neurovascular bandelet preservation), radical retropubic prostatectomy is associated with the risk of severe complications (bleeding, urinary incontinence and erectile dysfunction). The aim of this study was to evaluate the experience with these first cases of radical retropubic prostatectomy and to use it in patient counseling and optimizing therapeutic decision.

MATERIAL AND METHODS

In the interval January 2011 - December 2012 at the Iasi Clinic of Urology and Kidney Transplant, radical retropubic prostatectomy was performed in 23 patients. The retrospective study included the analysis of the significant data in the medical records, protocols, outpatient postoperative check-ups, with special emphasis on indications, intra- and early postoperative complica-

tions (within 30 days), and hospital stay.

Preoperatively, prostate cancer was generally diagnosed by at least six prostate biopsies. Routine staging included digital rectal examination, PSA determination, and magnetic resonance imaging or abdominopelvic computed tomography. Bone scintigraphy was performed in only 5 patients (21.7%) in which PSA values were higher than 10 ng/ml (tab. I) (1).

TABLE I

TNM staging (2009) adapted, with localized prostate cancer highlighted

T – Primary tumor
T1 Clinically inapparent tumor, neither palpable nor visible by imaging **T1a** Tumor incidental histologic finding in ≤5% of tissue resected **T1b** Tumor incidental histologic finding in >5% of tissue resected **T1c** Tumor identified by needle biopsy because of elevated PSA
T2 Palpable tumor localized intraprostatic **T2a** it involves less than half of a prostatic lobe **T2b** it involves more than half of a prostatic lobe **T2c** it involves both prostatic lobes
T3 Tumor extends through the prostate capsule **T3a** extracapsular extension, including microscopic invasion of vesical neck **T3b** invades seminal vesicle
T4 Tumor is fixed or invades adjacent structures, other than seminal vesicles: external sphincter, rectum, levator muscles and/or pelvic wall
N – Regional lymph nodes
N0 no regional lymph node metastasis
N1 metastases in the regional lymph
M – Metastasis
M0 no metastasis
M1 metastasis **M1a** nonregional lymph nodes **M1b** bone **M1c** other sites

Postoperatively, urethral catheter was removed 10-14 days after surgery if retrograde cystography showed no contrast extravasation at the anastomotic site. Patients were discharged the next day if the surgical wound was healed and they urinated spontaneously.

The urethral catheter was removed 10-14 days after surgery if retrograde cystography showed no contrast extravasation at the anastomotic site. Patients were discharged one day after catheter removal if the surgical wound had healed, and they urinated spontaneously.

RESULTS

Patient age ranged between 56 and 69 years with an average of 62.6 years, and preoperative PSA level was 4.5 to 27.2 ng/ml (mean 9.5 ng/ml). Gleason score was 5 in one patient (4.3%), 6 in 20 patients (87%) and 7 in 2 patients (8.7%). Three patients (13.1%) received neoadjuvant hormone therapy (LH-RH analogues/antiandrogens) (tab. II).

The neurovascular bandelets were preserved in 19 patients (82.6%), bilateral in 13 (56.5%) and unilateral in 6 (26.1%). Pelvic lymphadenectomy was performed in one patient (4.3%).

Intraoperative blood loss was 400-2500 ml, with an average of 1214 ml, 17 patients (73.9%) requiring blood transfusion.

TABLE II

Clinical stage distribution

Clinical stage	Patients	
	No.	%
T1c	5	21.7
T2a	7	30.4
T2b	3	13.1
T2c	6	26.1
T3a	2	8.7

No death was recorded in the study group. In 14 patients (60.1%), postoperative course was simple, without complications. The complications, most of them minor, recorded in 9 patients (tab. III).

TABLE III

Postoperative complications

Complications	Cases	
	No.	%
Acute renal failure	3	13.1
Extravasation of contrast media (retrograde cystography)	3	13.1
Urinary infection	4	17.4
Surgical wound dehiscence	1	4.3

Urine loss following urethral catheter removal ranged between 30 and 1510 ml/day, with an average of 396 ml/day, but decreased 30 days postoperatively to an average of 204 ml/day (0 - 650 ml / day). Mean postoperative hospital stay was 19.57 days (range 13-43 days).

DISCUSSION

To determine the prognosis of the patients diagnosed with PC we applied the Partin tables (James Buchanan Brady Urological Institute, Johns Hopkins Medical Institutions, Baltimore, USA) and MSKCC nomogram (Memorial Sloan-Kettering Cancer Center, New York, USA), which are commonly used worldwide prior to initiating treatment.

The Partin tables use the clinical features of PC (Gleason score, serum PSA and clinical stage) to determine the likelihood of localized disease and the risk of extracapsular extension, seminal vesicle and regional lymph node invasion (2).

Pre-treatment MSKCC nomogram uses the following data: PSA value, Gleason score, clinical stage, number of positive and negative biopsies and possible neoadjuvant treatments (hormonal, radiation). The results obtained after processing the above data are

used to calculate the likelihood of malignant disease extension (localized disease, extracapsular extension, seminal vesicle and regional lymph node invasion) and the evolution after curative-intent therapy (5 and 10-year progression-free and 10 and 15-year cancer-specific survival). Progression-free survival means that PSA levels remain undetectable and PC will not progress after radical prostatectomy (3); cancer-specific survival estimates the likelihood of surviving prostate cancer within 10-15 years of radical prostatectomy (4).

The mean probability of localized disease (61.1%) and the risk of extracapsular extension (31.6%), seminal vesicle invasion (5.3%) and regional lymph node invasion (1.9%), as it results from the use of the Partin tables and the mean probability of localized disease (63.2%), extracapsular extension (30.6%), seminal vesicle invasion (8.8%) and regional lymph node invasion (3.7%) as it results from the use of MSKCC nomogram. Note the similitude in values and graphical presentations between the two techniques for assessing prognosis in prostate cancer patients (fig.1, fig.2).

Prognosis after radical prostatectomy calculated using MSKCC nomogram was encouraging; thus progression-free survival at 5 and 10 years was likely in 92.2% and 88.7% of the patients, respectively, while cancer-specific survival at 10 and 15 years was 99% (fig.3).

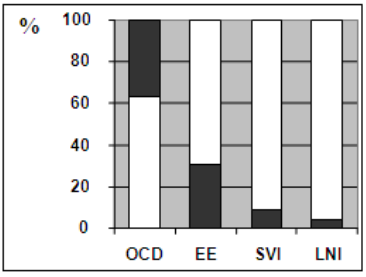

Fig. 2. Mean probability of organ-confined disease (OCD), extracapsulare extension (EE), seminal vesicle invasion (SV1) and reginal lymph node invasion (LNI), MSKCC nomogram

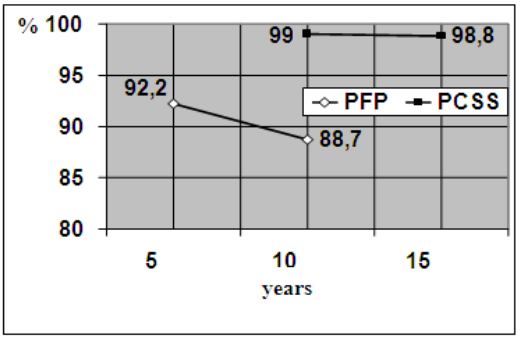

Fig. 3. Progression-free period (PFP) and cancer-specific survival Prognosis after radical prostatectomy, calculated by MSKCC nomogram)

Three patients (13.1%) developed acute renal failure in the early postoperative period, but it was rapidly resolved after hydroelectrolytic rebalancing.

Retrograde cystography revealed extravasation of contrast medium in 3 patients, requiring prolonged bladder catheterization.

Pelvic lymphadenectomy was performed in but one patient, the remaining patients being at low risk for dissemination according to the prognostic algorithm.

Besides the curative role of radical retropubic prostatectomy, patient quality of life, depending on the incidence of intra- and postoperative complications, especially of those with long-term impact (urinary incontinence, impotence) is a major aspect of this surgical technique (5).

Despite the small number of cases, our results are similar to those in the literature (5). This can be explained by the strict patient selection in terms of therapeutic indication and low level of co morbidities.

Three (13.1%) patients developed acute renal failure in the early postoperative period, rapidly resolved after electrolyte rebalancing. Extravasation of contrast material, demonstrated by retrograde cystography in 3 patients, required extended bladder drainage by urethral catheter. The 4 patients (17.4%) with postoperative urinary infection received specific antibiotic therapy and the patient with surgical wound dehiscence had secondary suture.

Pelvic lymphadenectomy was performed only in one patient because the remaining patients were at low risk for dissemination according to the prognostic algorithm.

CONCLUSIONS

Radical prostatectomy is considered the best therapeutic option in organ-confined PC for patients whose life expectancy is at least 10 years (6). The initial experience of the Iasi Urology and Kidney Transplant Clinic confirms this, also underlying the relatively low rate of intra-and postoperative complications.

SURGICAL-ORTHODONTIC TREATMENT OF MALOCCLUSIONS THROUGH BEGG TECHNIQUE (Abstract): **Aim**: To assess the effectiveness and quality of surgical-orthodontic treatment outcomes through Begg technique in patients with malocclusions. **Material and methods**: Of a total of 117 patients referred to the Orthodontics Clinic Iasi, 16 patients with malocclusions (7 boys and 9 girls) were selected according to certain criteria and received surgical and orthodontic treatment through Begg technique. The outcomes were assessed clinically and radiological. Statistical analyzes were performed in *SPSS 16.0* for Windows. **Results**: 56.2% of the patients presented Angle Class I malocclusion, 12.5% Class II/1, and 31.3% Class II/2. Orthodontic therapeutic extractions were performed symmetrically on maxillary and/or mandible in 12 patients: first premolars in 18.8%, second premolars in 37.5%, or permanent first molars in 18.7%. Following extraction all patients were treated with Begg appliances. The duration of active treatment stages was variable, depending on stage results and some individual inconveniences. After five years, the therapeutic outcomes were stable, there were no post-treatment relapses, and the degree of root resorption of upper incisors that occurred in 60% of the patients was low. **Conclusions:** The indications of the orthodontic treatment through Begg technique have some limitations, the dental and periodontal response varied from patient to patient, major post-treatment root resorptions did not occur, and the assigned time was on average 6 month longer. **Keywords:** BEGG TECHNIQUE, MALOCCLUSIONS, PERMANENT TEETH EXTRACTIONS, ROOT RESORPTION.

Begg technique (TB) (1, 2, 3) is an original method that uses an arch-bracket system and a completely different treatment philosophy than Tweed system.

The basic principles used by Begg were the concept of attritional occlusion, differential force system, and the use of light orthodontic forces, and in collaboration with A. Wilcock (cit.1) the best alloy for orthodontic springs was developed. By the use of light orthodontic forces, this technique does not require extraoral anchorage, but it may be associated with minor oral surgery (extractions of permanent teeth for orthodontic treatment) and removable appliances.

Begg technique had been evolving over two decades, when many experts have adopted and developed system of brackets, archwires and auxiliary devices (3). In America and Europe it received wide popularity in the '70s, and had a considerable decline due to poor dental dimensional control (4). Currently this technique is practiced sporadically worldwide despite

its low cost, largely due to time-consuming archwire adjustment by the orthodontist.

We have assessed the surgical-orthodontic treatment by Begg technique in a series of patients with malocclusion in view of testing its effectiveness and the quality of treatment outcomes and compared them with results reported by other authors.

MATERIAL AND METHODS

The study was conducted on 16 patients (7 boys and 9 girls) with malocclusion, aged 12 to 19 years. They were selected from 117 patients according to the following criteria: age over 12 years, complete eruption of permanent molars, no dysfunction or vicious habits, and absence of Angle class III malocclusion. After obtaining the informed consent, all patients were subjected to clinical and laboratory examinations (model, photostatic, orthopantomography and lateral cephalometry studies) and surgical-orthodontic treatment by Begg technique.

Surgical extraction for orthodontic purposes or non-extraction was decided depending on space requirements and odontal status. Dental extractions were performed in the Clinic of Oral and Maxillofacial Surgery of the Iasi "St. Spiridon" University Emergency Hospital.

Patients were examined at each intermediate stage of treatment, at the end of retention period, and then annually for five years. The final results were assessed clinically. STRATO-X orthopantomograph with magnification factor of 11.8% was used for radiographic evaluation of the degree of root resorption of upper incisors, measuring directly on pre- and post-treatment retroalveolar radiographs the root height (distance from anatomic neck to apex).

Database and statistical analyzes were performed in SPSS 16.0 for Windows and descriptive statistics was used. Results were displayed in MS Excel.

RESULTS

Of the 16 randomized patients 56.2% (n = 9) presented Angle Class I malocclusions and 43.8% (n = 7) Angle Class II, of which 12.5% Class II/1 (n = 2) and 31.3% class II / 2 (n = 5) (fig. 1).

Minor oral surgery was initiated three weeks before the start of orthodontic treatment and extractions for orthodontic purpose were performed in 12 patients. To make space on arcades, tooth extractions were symmetrical on maxillary and/or mandible. To select the appropriate sites of orthodontic tooth extraction, facial esthetic criteria, odontal and periodontal status, facial growth pattern, and type of malocclusion were considered. Teeth selected for extraction were the first premolars (3 patients), second premolars (6 patients) or permanent first molars (3 patients) (fig. 2).

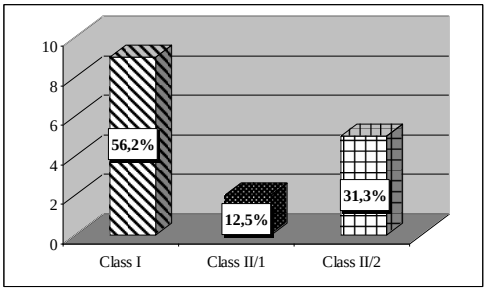

Fig. 1. Frequency of malocclusion types

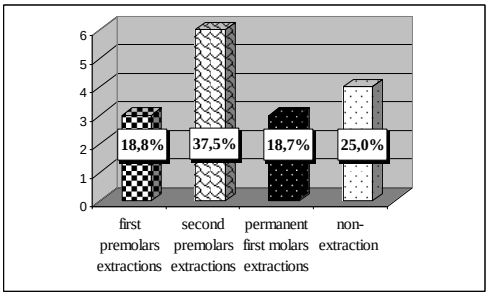

Fig. 2. Frequency of minor oral surgical treatment types

Orthodontic treatment was initiated simultaneously in the 16 patients. We used Begg-type fixed poly-aggregate appliances: orthodontic bands made with cylindrical and oval vestibular tubules and hooks on the molars, prefabricated brackets with vertical, round slots and pins for archwire fixation into brackets; main archwire, plain or looped, made by the orthodontist of two types of round cross section Australian wire (Regular and Special^{+}); second archwire for all types of root movements (derotation and uprighting), placed in bracket slot and attached to the main archwire; class I, II or III elastics. Begg appliance was placed monomaxillary (10 patients) and bimaxillary (6 patients), depending on the severity of malocclusions (fig. 3).

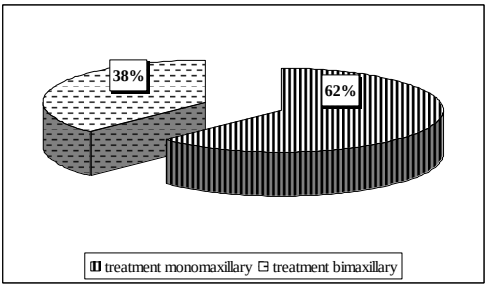

Fig. 3. Frequency of orthodontic treatment types

Orthodontic treatment was carried out in three active stages (alignment of teeth, spaces closure, uprighthing and torque), followed by retention period. The first stage of treatment had a mean duration of 9 months, during which crowding of teeth, frontal tooth rotations, overbite to an edge to edge relationship, open bite, crossbite, and axial relations of anchor permanent molars were corrected and spaces closed. The second stage of treatment lasted on average 7 months and was aimed at extraction space closure, distal tipping of the incisor crowns, over-correction of derotations, and completion of tooth movement. The third stage of treatment had a mean duration of 14 months and consisted in corrections of the mesiodistal, axial and vestibulo-oral relations, completion of over-corrections of derotations, and completion of tooth movement. Retention was achieved with such passive appliances as Hawley retainer and had a mean duration of 12 months (fig. 4).

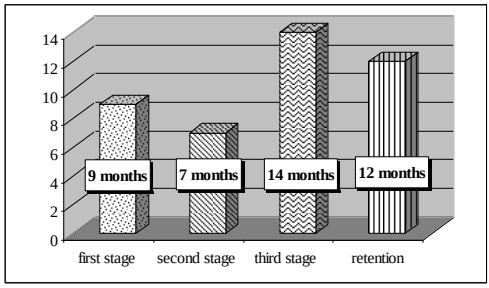

Fig. 4. Duration of orthodontic treatment stages

During treatment some subjective and objective problems have occurred, which prolonged the individual duration of orthodontic treatment. Some patients did not follow the monthly activation appointments, proper nutrition, good oral hygiene, frequently resulting in loosened brackets, ruptured rigid ligatures, arches deformed by chewing, band decementation, and gingival inflammation. In patients with rotation of inferior canine teeth and extractions of permanent lower first molars, rotation of lower second molars and early eruption of lower third molars required the simultaneous use of some removable appliances to increase control over second molars mezialization. In other patients there were excess space and periodontal reactions. Of the 16 patients, one abandoned treatment for aesthetic reasons.

Post-treatment results were stable over the 5 follow-up years in all patients and

there were no recurrences. Radiographically, the degree of root resorption of upper incisors was between 2-4 mm in 4 patients, between 1–2 mm in 5 patients, and undetectable or below 1 mm in 6 patients (fig. 5).

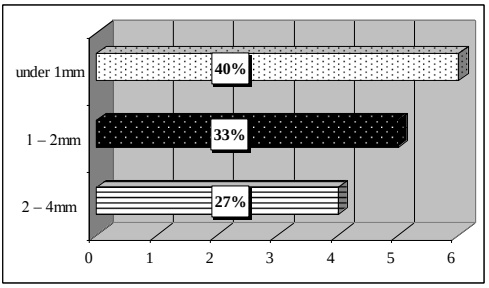

Fig. 5. Post-treatment degree of root resorption of upper incisors

DISCUSSION

In orthodontic practice, Begg technique, together with Edgewise technique, is a basic technique of fixed polyaggregate treatment. Begg technique is simpler and less expensive than Edgewise technique (1, 2, 3).

For a successful orthodontic treatment, Begg said that essential are a complete and correct diagnosis and individualized treatment protocol for each clinical case.

Our study patients presented dental and/or skeletal abnormalities specific to our population, in agreement with Begg's initial indications. Angle class III skeletal abnormalities were excluded from the study, because these are one of the limitations for application of Begg technique.

Controversy over extraction prior to orthodontic treatment and non-extraction has not yet been elucidated. Begg was in favor of extraction of four first premolars, application of the polyaggregate system three weeks later, and use of Class I, II and III elastic traction. Tooth extractions solve the need of space in frontal area in Angle class I or Angle class II incisive protrusion by applying in the first stages of treatment of elastic tractions that induce distoversion of canine teeth, and in the third stage of treatment of secondary archewires that causes root movements in the opposite direction and closure of extraction spaces (2).

Some of our study patients presented severe dental clinical situations, complicating the treatment plan by the absence of a second premolar or permanent first molar, which required the selection of other teeth for symmetrical extractions on two or four dental quadrants. For these reasons, in some patients treatment stages were longer and there were some unwanted dental movements of the permanent second molars, solved by the use of movable devices.

Begg appliance has the advantage of light orthodontic forces, minimal brackets-main archwire friction, rapid teeth alignment, dental occlusion opening, minimal oral anchorage, and low cost. Disadvantages are related to complex archwire modeling, difficult positioning of secondary arches, imprecise three-dimensional teeth control, absence of rectangular arches, monthly activation appointments, and inestethic components.

In our study patients, the duration of intermediate stages of treatment was short, but the finishing stage required a longer period of time due to the poor control of teeth positions by single-point brackets, as mentioned by Swain (5).

Some problems occurring during treatment were mentioned in the literature and determined changes in Begg appliance. Thus, the following were introduced: segmental arches, used in Edgewise technique for canine distalization (6), separate arch system for extraction and non-extraction cases (7), and Edgewise brackets on the front group and rectangular wire (8), which were beneficial to control tooth movement.

Dermaut and De Munck (9) have

demonstrated that there is an obvious correlation between the degree of tooth intrusion and root resorption. Scott and Green (10) have studied the phenomenon of root resorption after orthodontic appliance removal and concluded that it does not correlate with tooth movements during active treatment, but with other factors (traumatic occlusion, wearing retention devices). McFadden et al. (11) found that root resorption was present in some teeth before treatment due to increased individual susceptibility, and that after treatment with Begg appliance, root resorption was 95% in lower incisors, 90% in upper central incisors, 87% in upper lateral incisors, and between 79 and 72% in canine teeth.

Due to the use of light forces, the degree of root resorption in the incisive group was low and affected a small percentage of patients. The obtained results were stable over time, without significant changes five years after treatment. Forty percent of the patients experienced varying degrees of resorption (1, 2), similar with the data reported in the literature (12).

CONCLUSIONS

Researches have shown that not all malocclusions can be treated by Begg technique, and when associated with extractions, the dental and periodontal response varies from patient to patient. This technique does not cause large amount of root resorption, but time for treatment is on average 6 months longer than with other fixed techniques.

ACKNOWLEDGEMENTS

The author gratefully thanks Prof. Valentina Dorobăț, Ph.D., Clinic of Orthodontics, Outpatient Clinic of the „St. Spiridon" Emergency University Hospital" University, Dr. Marjolein Zijlstra-Mondt and Dr. Else Marjan Groenman from the Netherlands for introducing Begg technique in Romania, and Stiling Friesland Foundation Roemenie - President Dr . H. Venema - for sponsoring orthodontic materials.

NEUROPEPTIDE Y STIMULATION AS PRIMARY TARGET FOR PREVENTIVE MEASURES OF MALADAPTATIVE CARDIOVASCULAR REACTIONS IN OCCUPATIONAL CHRONIC STRESS EXPOSURE (Abstract): Chronic stress may produce a decrease in central NPY expression and subjects exposed to it may prove hypersensitivity to a novel stressor with dysfunctions in the NPY system and cardiovascular maladaptation to stress, even hypertension. Upregulation of NPY expression may contribute to successful behavioral adaptation to stress by reducing cardiovascular tone and suppressing anxious behaviors. Adaptogens, a new class of metabolic regulators stimulate NPY expression and release. **The aim** of this study is to increase tolerance and adaptation to stress of hypersensitive to novel stressor, occupational chronic stress exposed subjects with cardiovascular maladaptation to mild new stressor using adaptogens as part of prevention protocol. **Material and methods:** 40 military personnel with known cardiostressor reactional mode and occupational chronic stress exposure were exposed to mild novel stressor: occupational medicine routine evaluation and clinically assessed for maladaptative cardiovascular response prior and before application of 30 day prevention protocol. Employees were randomly split in two groups, one receiving standard prevention protocol (lifestyle counseling) plus adaptogens in multiple dose administration, twice daily and the other receiving only standard prevention protocol. **Results:** We found significant statistic differences in all cardiovascular parameters in adaptogen group and only in diastolic blood pressure in control group. **Conclusions:** Adaptogens could be an important factor in successful prevention protocols of chronic occupational stress dysfunctions involving NPY systems. **Key words**: NPY, ADAPTOGENS, CHRONIC OCCUPATIONAL STRESS, CARDIOVASCULAR MALADAPTATION, NOVEL STRESSOR

Neuropeptide Y (NPY) is a central neuromodulator and peripheral sympathetic neurotrans mitter with significant regulatory roles in cardiovascular, neuroendocrine, immune and metabolic adaptation to stress and its release has been linked to a variety of stress-induced changes whose actions are dependent on the activation of multiple G-protein-coupled receptors,Y1-Y5 (1). In the brain the concentrations of NPY are significantly higher than other neuropeptides , being found mainly in the limbic system, including amygdala and hypothalamus, areas known for regulation of emo-

tional behaviours and stress response (2). Central, NPY acts as an anxiolytic and inhibits sympathetic activity with lowering blood pressure and heart rate resultants (3). Plasma NPY levels are positively related with behavioral performance under stress (4). Low plasma levels of NPY are associated with nervous autonomic system hyperactivity to stressors, hyperarousal, exaggerated alarm reactions and anxiety reactions (5). Chronic stress may produce a decrease in NPY expression in several central nervous system regions (6) and chronic stress exposed subjects may prove hypersensitivity to a novel stressor (7) with dysfunctions in the NPY system that might lead to cardiovascular maladaptation to stress and even hypertension (8). Heilig and Thorsel proposed that an upregulation of NPY expression may contribute to successful behavioral adaptation to stress through its buffering of stress promoting signals (9) and later it was demonstrated that activation of NPY systems reduces cardiovascular tone and suppresses anxious behaviours (8). Adaptogens, a new class of metabolic regulators which increase the ability of an organism to adapt to environmental factors and to avoid damage from such factors, raising the state of non-specific resistance (10) were recently proved to stimulate the expression of NPY and its release from neuroglia cells as primary upstream target (11). Panossian et al. study was done using ADAPT 232, a combination of *Eleutherococcus senticosus* root extract, *Schisandra chinensis* berry extract and *Rhodiola rosea* root extract and they demonstrated that increased tolerance and adaptation to stress obtained through this formula might be due to stimulation and release of NPY into systemic circulation as an innate defense response (12). Standard occupational prevention programs of maladaptation to chronic stress concentrate on lifestyle changes and relaxation methods promotion.

MATERIAL AND METHODS

Our study is open label randomized type of study done on 40 military personnel, all males, recruited during routine occupational medical evaluations between February and March 2012, in occupational medical office from Emergency Military Hospital, Iasi. Research group was randomly split in two, 20 employees being the study group (SG) and 20 employess being the control group (CG). All signed informed consent and the selection was based on inclusion and exclusion criteria. The inclusion criteria were age between 25 and 50 years, being healthy, having no significant history, BMI- 18.50-24.99 kg/m2, stress reactive type- cardiostressor- arterial blood pressure $\geq$ 140/80 mmHg and rest heart beat >80 beats/minut. The exclusion criteria were cardiovascular disease, endocrine disease, neurologic disease, obesity, arterial blood pressure <140/80 mmHg and rest heart beat <80 beats/minute.

Military employees are prone to more maladaptative cardiovascular stress responses than general population (5) and percentage of such dysfunctions is quite significant as we found in previous studies done in our occupational medicine office. Recent studies on stress protective on stress protective effect of a combination of adaptogens- ADAPT 232- through NPY expression stimulation and release from neuroglia cells (11) incited us to determine if this combination of standardized adaptogens might be useful as preventive measure in maladaptation to occupational stress. We considered the occupational medicine routine evaluation a mild novel stressor and

cardiovascular dysfunctions finded(arterial blood pressure ≥ 140/80 mmHg and rest heart beat >80 beats/ minute) an exaggerated alarm reaction and anxious behavior of a chronic occupational stressed hypersensitive subject with low central levels of NPY (5). We selected apparently healthy male military employees with known cardiostressor reactional mode, aged 25 to 50 years and as told earlier in the text, they were randomly split in 2 groups. Girst group,SG group received a standardized combination of adaptogens – Adaptonic- *Eleutherococcus senticosus* root extract, *Schisandra chinensis* berry extract and *Rhodiola rosea* root extract from *Alevia*, *Falticeni*, multiple dose administration, twice daily and lifestyle counselling and CG group received only standard protocol that is lifestyle counselling . We hypothesized that stimulation of NPY through Adaptonic will improve tolerance to novel stressors in a chronic occupational stress exposed subject. Subjects were reevaluated 30 days after, being exposed to same mild stressor but with 30 days interference and we studied alarm reaction through cardiovascular parameters.

RESULTS AND DISCUSSION

We used descriptive statistic studies and TTEST from Microsoft Excel 2003. There were no significant statistic differences between the two groups on age parameter (35.60±7.38 years for SG compared with 35.95±8.17 years for CG. We found significant statistic differences ($p<0.05$) in all cardiovascular parameters (tab.I). Thus the stimulation of NPY through the combination of adaptogens- Adaptonic- improved tolerance to novel stressor in the chronic stress exposed subjects.

TABLE I

Cardiovascular parameters in study and control groups before (t0) and after 30 days of standard protocol and adaptogens (t1)

Group	N	Age(years)	Systolic blood pressure in t0 (mmHg)	Systolic blood pressure in t1 (mmHg)	Diastolic blood pressure in t0 (mmHg)	Diastolic blood pressure in t1 (mmHg	Rest heart rate (beats/min) in t0	Rest heart rate (beats/min) in t1
Study group (SG)	20	35,60±7.38	156.20±11.63	138.50±6.3	91.50±7.27	73.25±7.38	96.50±7.96	74.85±6.01
Control group (CG)	20	35.95±8.16	154.80±9.75	154±9.4	90.25±7.34	86.50±6.97	96.15±10.70	94.80±8.91

In group 2 we found significant statistic differences only in parameter: diastolic blood pressure ($p<0.05$). This finding could be due to prior experience of NPY systems to the mild stressor we used that is medical evaluation, taking in account that NPY influence vascular tonus but adaptation to the stressor is incomplete as cardiovascular parameters: systolic blood pressure and rest heart rate had no significant statistic differences ($p>0.05$) (tab. I).

Testing plasma levels of NPY as routine measure of occupational medical evaluation in chronic military stress exposed subjects, with cardiovascular maladaptation to mild novel stressor might bring important, adia-

cent information about their alarm reaction capacities and gives us the possibility to correct any dysfunction of the stress response system before the units are involved in high-stress, high-risk operations.

CONCLUSIONS

We found out that adaptogens could be an important factor in a successful preventive measures protocol of chronic stress dysfunctions involving NPY systems. Early diagnosis of these type of dysfunctions and their treatment with a combination of adaptogens might prove organizational and individual health saving. Extensive studies on larger populations and with different occupations are neede for further development of the treatment protocol.

EXTRAHEPATIC COMPLICATIONS OF CHRONIC CHOLESTASIS: CURRENT DIAGNOSIS AND TREATMENT (Abstract). Pruritus, fatigue and osteoporosis are the main symptoms of the extra hepatic manifestations of chronic cholestasis that affect patients' quality of life. Pruritus affects more often female patients, varies as intensity during a day and for longer period of time, typically can be localized on the palms of hands and soles of feet or can be generalized. Pruritus can be treated with anions resines exchange – cholestiramine, the pregnanne X receptor agonist Rifampicine, Naltrexone. Liver transplantation can be considered if severe pruritus remains refractory to all medical treatments. Fatigue is the most disabling complain in chronic colestasis. No specific therapies are available for fatigue and liver transplantation doesn't improve it. Osteoporosis and the risk of fractures are more severe with the duration and severity of hepatic disease. For treatment are recommended regular physical exercise, vitamin D and Ca supplimentation and bisphosphonates (Alendronate 70 mg/week) in severe cases. Only patients with atherosclerotic risk and hyperlipemia can be treated with statines. Fat soluble vitamin supplementation can be administrated only in symptomatic and proved vitamin deficiency. **Key words**: CHOLESTASIS, PRURITUS, FATIGUE, OSTEOPOROSIS

Intrahepatic chronic cholestasis is not just an isolated disease but a complex process resulting from a number of hepatic conditions, such as primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC), drug-induced cholestasis, idiopathic biliary ductopeny in adults, cholestasis of pregnancy, cystic fibrosis, sarcoidosis, granulomatous hepatitis and HIV-associated cholestasis.

Complications of chronic cholestasis can be classified as hepatic (portal hypertension, ascites, encephalopathy, liver failure) and extrahepatic - frequent (pruritus, fatigue, osteoporosis, hyperlipidaemia, malabsorption of fat-soluble vitamins and steatorhhea) and rare (peptic ulcer, hyperpigmentation). Usually, extrahepatic complications of cholestasis are not fully appreciated. Their identification, early diagnosis and prophylactic or curative treatment leads to improvement in quality of life in patients with chronic cholestatic liver disease.

PRURITUS

Pruritus and lethargy are the commonest

extra hepatic manifestations of chronic cholestasis. In patients with cholestasis pruritus can represent either a minor problem, or on the contrary an extremely significant one, leading to loss of quality of life, attention deficit, social inconvenience, insomnia, poor intellectual function, depression or even suicide. Disabling chronic pruritus is an indication for liver transplant if all other therapeutic measures have failed (1, 2).

Pruritus in chronic cholestasis has a variable intensity throughout the day, as well as over longer periods of time. It is usually worst at night. It may also demonstrate a circadian variation, being worse in the afternoon (3). It usually affects the palms and feet and is not associated by characteristic skin lesions (4). Scratch marks secondary to pruritus can lead to eczema, skin changes, secondary bacterial infections and even sepsis (5).

Pruritus in chronic cholestasis diminishes in the final stages of chronic liver disease and appears to be inversely proportional to severity of cholestasis. It is more common in women compared to men. Its prevalence varies according to the chronic conditions that evolve with cholestasis. In PBC and PSC it is found in 25 – 80% of cases and in 5 – 15% of hepatitis C sufferers. In chronic hepatitis B and steathohepatitis pruritus is not usually manifested, despite the presence of cholestasis (6).

Etiology

The etiology of pruritus in chronic cholestasis is yet to be identified. The cholestatic liver appears to synthesize pruritus-inducing substances either directly or as cofactors (7). Pruritus has been attributed to a number of agents in the absence of any solid evidence: bile salts, steroid hormones, endogenous opioids, histamine and serotonin (8). Current research is focusing on autotaxine and its product lysophospatidic acid.

Bile salts were first associated with pruritus in cholestasis; however, the following were demonstrated:

- The level of serum, urine and skin bile salts does not correlate with the severity of pruritus;
- Low levels of bile salts are found in cases of severe pruritus.

A good example is that of pruritus in PBC. This can be severe in moderate forms of the disease (where bile salt levels are not significantly elevated) and minor or absent in severe forms (in the presence of high levels of bile salts). In conclusion, bile salts and their metabolites could have an indirect role in the etiology of pruritus in cholestasis (9).

Steroid hormones and their metabolites could be cofactors in cholestatic pruritus. This may be suggested by a higher prevalence of cholestasis in women and its presence in pregnancy, where pruritus is most intense in the third trimester where steroid hormones and their metabolites reach the highest concentrations. After delivery, the level of steroid hormones decreases together with pruritus, as well as the reduction in cholestasis parameters (10). It has been hypothesized that steroid hormones might modulate neuronal excitability of pruritus-mediating and/or nociceptive fibers in patients with cholestasis (6).

Endogenous Opioids. Although the administration of opioids can lead to pruritus, no relationship has been established between opioid concentration and intensity of pruritus. This is exemplified by a similar level of opioids present in PBC patients with and without pruritus (10). At present it is unclear how endogenous opioids lead to pruritus.

Histamine levels are raised in chronic cholestasis – however sufferers do not

respond to antihistamine therapy. Furthermore, skin changes associated with histamine release (erythema and urticaria) are missing in patients with cholestasis and pruritus. It is therefore unlikely that histamine is involved in the etiology of cholestatic pruritus (6).

Serotonin is not considered a mediator of pruritus, although cholestasis alters serotonin homeostasis, and consequently the perception of pruritus.

Lysophospatidic acid (LPA), being a potent neuronal activator, has the potential to cause pruritus in cholestasis. Studies have demonstrated that the serum level of ***autotaxine*** (LPA forming enzyme) is raised in patients with cholestasis, and is directly proportional with the intensity of pruritus (1).

Therapy

The Etiology of pruritus remains unknown. Despite this, many agents have demonstrated total or partial therapeutic benefit:

1. Drugs that bind or increase faecal excretion of pruritus-mediating agents: cholestyramine, colestipol and colesevelam. *Cholestyramine, colestipol and colesevelam* are anion exchange resins which bind pruritus-mediating substances and aid their faecal excretion. They bind bile salts in the bowel lumen, interrupting the enterohepatic circulation and leading to increased synthesis of bile salts from cholesterol in hepatocytes. Cholestyramine was the first drug used for the effective treatment of pruritus and remains a first line therapeutic agent, leading a reduction or even resolution of symptoms in 2 – 4 days. Recommended doses are 4 – 16 g / day (1, 6). Any other therapeutic agent can be bound by anion exchange resins (thryoxine, digoxin, oral contraceptives, ursodeoxycholic acid, etc) and these must be taken at least 2 – 4 hours prior to cholestyramine. Adverse reactions of cholestyramine include metallic taste, bloating, constipation, worsening of fat malabsorption and fat-soluble vitamins (2,10,12). Colestipol and colesevelam have not been investigated in clinical studies, and cannot therefore be recommended as first line therapy (13).

2. Enzyme inducers. *Rifampicin* is an enzymatic inducer and agonist of pregnane X receptor (PXR). It is used as second line therapy of cholestatic pruritus; it can be administered as first line therapy in those who cannot tolerate cholestyramine (1). Mechanism of action include (14): competing with bile acids for hepatocyte uptake; decreasing the intracellular concentration of bile acids, as well as their detergent activity on cell membranes; induce microsomale enzymes facilitating urinary excretion; modify gut flora leading to disturbance of the bile salt metabolism and that of pruritus-mediating substances. Pruritus subsides in less than a week from commencement of therapy. Doses administered are 150 mg/day if bilirubin is under 3mg/dl and 150 mg twice daily if bilirubin levels are greater than 3 mg/dl (2, 6); doses can reach up to 600 mg/day (1). Many adverse reactions have been described, affecting 12% of cases 2-3 months following treatment (12). Severe and frequent reactions include: drug-induced hepatitis, hemolytic anemia, renal failure and thrombocytopenia (15, 16). Due to these side effects initial doses must be low and carefully monitored once increased.

3. Therapy with agents which interfere with opioid neurotransmission represents third line therapy, according to European and US guideline. Cholestasis related pruritus is associated with a rise in opioidergic tonus, which interacts with opioid-mediated neurotransmission in order to reduce pruri-

tus. *Naltrexane* is an oral opioid antagonist which, according to literature meta-analyses, leads to effective reduction in pruritus (17). It is administered in increasing doses, starting with 12.5 mg. The dose is increased by 12.5 mg at 3-7 days until the pruritus is controlled. The maximum dose is 50 mg/day. Inpatients may be given IV *naloxone* 4 mg twice or three times per day, followed by *naltrexane* (1,6).

The use of opioid antagonists is limited by withdrawal-like reactions, which occur spontaneously and unpredictably. Some data suggest that these reactions may relate to the severity of the pruritus (18), although there is a lack of consensus. These reactions manifest as abdominal pains, a rise in arterial blood pressure, tachycardia, nightmares and depersonalization. Prolonged use may be associated with chronic pain syndrome (19). Patients must be monitored both clinically for the above mentioned adverse reactions, as well as biochemically due to potential liver toxicity.

4. Anti-depressants. According to the EASL guide, *sertraline* is a fourth line therapeutic agent, belonging to the antidepressesant class of drugs. It is a selective serotonin receptor inhibitor. Doses of 75 – 100 mg/day lead to almost complete remission of pruritus, independent of its antidepressant side-effects. The mechanism of action is not fully understood (20). Antipruritic results in patients with chronic cholestasis obtained with opioid antagonists and sertraline are inferior compared to those seen in patients treated with cholestyramine and rifampicin – these remain first and second line therapeutic modalities, respectively.

5. Extra-corporeal dialysis with albumin and plasmaphoresis are recommended in cases of disabling pruritus, resistant to therapies mentioned previously. Initial therapy involves 3 sessions per week and gradually is decreased to one session per week. This acts predominantly on unidentified plasma pruritus-mediating substances (12, 21, 22).

6. Liver transplant is indicated in pruritus caused by chronic cholestasis resistant to all other therapeutic measures mentioned above, having an increased risk of depression and suicide (23).

7. Other therapies used include anabolic hormones, dexamethasone, phototherapy, serotonin antagonists (ondansetron). Currently their value is only historical. *Androgenic steroids* (*norbetalon, methyltestosteron*) were used for a short duration. They act at a hepatocellular level. Their adverse reactions (worsening of cholestasis, virilisation, growth disturbances, and increased risk of hepatocellular carcinoma) and lack of benefit in improving choelstasis and pruritus lead to their removal from current therapeutic strategies (24). *Dexamethasone* was used in large doses (12 mg/day) in pregnancy-induced cholestasis. *Gabapentin* and *cimetidine*, similar to dexamethasone, have no proven effect in improving pruritus associated with chronic cholestasis. The presence of adverse reactions led to discontinued use. *Phototherapy*: ultraviolet light led to improvements in pruritus secondary to cholestasis. Starting from this observation, progressive exposure to ultraviolet light can decrease pruritus, but increases the risk of skin cancer. *Antihistamine therapy* is less effective (chronic cholestasis-associated pruritus is not associated with histamine release). Similar to *phenobarbital*, these have a sedative effect, and both address the insomnia associated with pruritus (1, 6). The use of phenobarbital can be associated with gingival hyperplasia. Antihistamine therapy can lead to dry oral mucosa, limiting their use in

chronic cholestasis associated with *sicca syndrome* (12). *Serotonin antagonists*: sfklmerotonin is involved in nociceptive neurotransmission. Ondansetron 4-8 mg three times per day, a serotonin type 3 receptor antagonist, has been used to treat chronic cholestatic pruritus without obvious improvements (25).

FATIGUE

Fatigue, together with pruritus, is a common symptom in chronic cholestasis. It has been predominantly studied in PBC (26). Tiredness in chronic cholestasis is not related to the severity of chronic liver disease and is not improved by liver transplantation (1). In order to attribute fatigue to chronic cholestasis, other concomitant pathologies need to be excluded, such as anemia, hypothyroidism, electrolyte abnormalities, diabetes, and depression.

Similar to pruritus, fatigue can be explained by changes in central serotonergic neurotransmitters (1). Different mechanisms have been suggested to explain fatigue, such as aberrant release of corticotrophin releasing factors (CRH) and accumulation of magnesium in the globus pallidus (26). In PBC fatigue is associated with changes in the autonomic nervous system (postural hypotension) and sleep disturbance, especially during the day (27).

Currently there is no available therapy specific for the fatigue associated with chronic cholestasis. In PBC studies have shown a reduction in daytime somnolence and objective tiredness (quantified through various scales and questionnaires) by using *Modefenil* 100 - 200 mg/day (28, 29). Psychological support and antioxidant therapy are required, as well as avoiding activities which exacerbate dysfunction of the autonomic nervous system (careful monitoring anti-hypertensive medication) and avoiding of sleep disturbance (avoiding coffee consumption in the afternoon) (1, 30).

BONE PATHOLOGY IN CHOLESTASIS

Osteodystrophy in cholestasis is mainly a consequence of osteoporosis and less one of osteomalacia (31). *Osteoporosis* represents a decrease in bone volume as a consequence of bone thinning with changes in micro architecture and a rise in the risk of spontaneous fracture. *Osteomalacia* is a defect in bone demineralization, secondary to a lack of vitamin D.

The majority of studies indicate that osteoporosis in chronic cholestasis has a moderate prevalence of 35%, with a wide range (9 – 90%), according to diagnostic criteria used and the degree of liver disease (32). Fractures secondary to osteoporosis have a prevalence of 2- 20% (33). The significance of osteoporosis and the risk of fracture increases with the severity and duration of hepatic cholestatic disease (1, 34). Other risk factors for osteoporosis independent of liver disease are: history of bone fractures, early menopause, and prolonged steroid therapy or with ion exchange resins, and not least alcohol consumption and smoking (34).

Disease mechanisms involved in the development of osteoporosis in cholestasis are not entirely clear. Some studies suggest impaired mechanisms of bone resorption, whilst others advocate changes in bone formation (35). High levels of osteoprotegerine in PBC seem to counterbalance the osteoclastic activity mediated by RANKL (Receptor activator of nuclear factor kappa-B ligand) (36).

The most accepted form of identifying osteoporosis involves the measurement of bone density through the biophotonic absorption of x-rays (DXA) in the vertebral

spine (L2 – L3) or in the superior segment of the femur. This method is quick, precise, reproducible and minimally invasive. Results are expressed though the Z score (number of standard deviations - SD compared to normal values in a person of similar age and sex) or T score (number of standard deviations from a absolute value in a young individual). According to the T score, the World Health Organization (WHO) classifies bone density in 4 levels:

Normal bone density - T score < -1 SD

Osteopenia - T score between -1 and -2.5 SD

Osteoporosis - T score < -2.5 SD

Severe osteoporosis - T score < -2.5 SD and at least one osteoporotic fracture

In addition to DXA assessment, a number of other parameters need to be quantified when monitoring of osteoporosis: calcium and phosphate metabolism, 25 OH – Vitamin D and parathyroid hormone. These need to be determined at the beginning of the assessment and at subsequent intervals (6 months to 3 years) according to the severity of cholestasis (1,12,32,37).

Therapy can be classified as being is prophylactic or curative.

Prophylactic treatment includes identifying and treating extra-hepatic risk factors previously described. Physical exercise, calcium and vitamin D intake and dietary supplements (Calcium: 1000 – 1500 mg/day; Vitamin D: 260 μg 25- OH vitamin D every 2 weeks or 400-800 IU/day) (32).

Currative tratement is commenced if DXA values are under -1.5 in the presence of previously mentioned risk factors or if the DXA score is ≤ 2.5 (1,12). *Bisphosphonate* non-hormonal therapies can also be used. Alendronate (70 mg/week for 2 years has an anti-resorptive effect, causing a rise in bone density and a decrease in the number of fractures (38). *Oestrogen based hormones* are no longer used due to hepatotoxic effects, whilst *calcitonin* therapy has been discontinued due to lack of treatment effect. Current evidence does not support the use of *Zolendronic acid* and *strontium* in the management of osteoporosis in cholestasis (12).

HYPERLIPIDAEMIA AND RISK OF ATHEROSCLEROSIS IN CHRONIC CHOLESTASIS

Studies investigating the risk of hyperlipidaemia in chronic cholestasis were predominantly performed on patients with PBC (39). These studies have shown that hypercholesterolemia in chronic cholestasis is not associated with clinical or subclinical atherosclerosis in a manner different from that in the general population (1, 2). Usually, in patients without cholestasis, the risk of atheroma formation is raised if the level of HDL cholesterol is low and LDL cholesterol levels are raised. In chronic cholestasis in PBC there are three factors with raised values and protective effects regarding the risk of atheroma formation in hyperlipidaemia: LpX originated from the oxidation of LDL and maintains it at a low level, HDL cholesterol and adiponectine. Consequently, only patients with chronic cholestasis with risk factors for atheroma formation benefit from therapy (39 – 41). Treatment consists of lifestyle changes (weight loss, physical activity, a good diet regarding cholesterol levels, etc) and medical therapy. *Statins* reduce LDL cholesterol, with minimal hepatic toxicity. They can be used in this group of patients in order to improve cholesterol levels. *Fibrates* (normally reduce the absorption of cholesterol, reduce inflammation and the production of antibodies) have not been shown to be efficacious in dyslipidaemias seen in chronic cholestasis (42). Current research

is investigating the role of *Ezetimibe*, which inhibits the intestinal absorption of cholesterol (Niemann Pick C1 like protein). This alone or in combination with statin reduces LDL cholesterol in cholestasis (43, 44). A promising therapy in dyslipidaemia in cholestasis is the *nuclear receptor inhibitors* which impact on cholesterol metabolism, the synthesis of bile acids and hepatic mechanisms of detoxification in chronic cholestasis (45).

MALABSORPTION OF FAT SOLUBLE VITAMINS (A, D, E, K)

A healthy adult stores 500,000 units of **vitamin A** in the liver as retinol – this reserve lasts 12 months. Symptomatic deficits of vitamin A are unusual in adults with cholestasis (46).

The assessment of vitamin A status in cholestasis is difficult and requires measurement of serum retinol levels, serum retinol/retinol binding protein, as well as ophthalmological assessment of adaptation to night vision. Asymptomatic deficit of vitamin A can be corrected using 15,000 U / day, followed by 45,000 U twice weekly. In symptomatic deficits, 100,000 U of retynil palmitate are administered IM every 2 months for 6 months, followed by oral vitamin A supplementation of 45 – 50,000 U twice weekly (47). Vitamin E aids the intestinal absorption of other fat-soluble vitamins and is recommended as an adjuvant in vitamin A deficiency (11).

Vitamin D. Vitamin D requires bile acids in order to be intestinally absorbed. Furthermore, vitamin D is transported in blood bound to proteins synthesized in the liver – patients with liver disease and biliary stasis do not produce sufficient transport proteins. Vitamin D levels are determined by serum measurement of 25-OH vitamin D levels (normal levels 35 – 55 μg/ml). Osteomalacia is the clinical manifestations of vitamin D deficit. Treatment consists of exposure to sunlight, physical exercise, monthly IM administration of 100,000 U vitamin D2 or D3 or daily oral administration of 50 – 100 μg 25-OH vitamin D. Vitamin D must not be given without adequate monitoring (47, 48).
